dissolution depending upon solution conditions such as pH, ionic strength and concentration of constituent ions. The dissolved mineral species can further interact with mineral solids, leading to surface conversion of the minerals. They can also interact with surfactant, leading to surface and bulk precipitation. All these processes can significantly affect the adsorption of surfactant on minerals. A full understanding of the various interactions in surfactant-solid-solution system is essential for developing efficient separation schemes. Indeed, desired selectivity can be achieved by using appropriate additives to control dissolved species or modifying collector adsorption and by optimizing solution conditions as well as the kinetics involved.

ION EXCHANGE

Catalysis: Organic Ion Exchangers

R. L. Albright, Albright Consulting,
Southampton, PA, USA

Copyright © 2000 Academic Press

Introduction

The ion exchange polymers most often used in catalysis are insoluble materials that can be constructed from inorganic or organic monomer units. This article will present only catalysis performed by the organic ion exchangers that are insoluble solids. There are commercial ion exchangers that are liquids, but to date they have been used very little in catalysis and, therefore, will not be included in this discussion.

Insoluble ion exchangers carry out their catalytic work in a heterogeneous rather than a homogeneous fashion and are, therefore, part of the group called heterogeneous catalysts. Heterogeneous catalysts have three very significant advantages over homogeneous catalysts: first, they are not corrosive; second, they are very readily separated from the reaction mixture by a simple filtration; and third, they are

most often recyclable from one run to the next without any added treatment. Potentially, they suffer one major disadvantage over homogeneous catalysts. Intimate contact between reactants and the catalytic site is not achieved simply by mixing the heterogeneous catalyst with the reactants. In a stirred reactor, intimate contact between reactants and the homogeneous catalyst is very easily achieved and mass transport of reactants to catalyst is very rapid and almost never rate-limiting. With heterogeneous catalysis, mass transport of reactants to the catalytic site may often be the rate-limiting element, especially if the activation energy for the reaction is small and the chemical reaction is rapid. There are excellent texts and monographs on the issues surrounding heterogeneous catalysis, and the reader is referred to these for the development of a fuller understanding (see Further Reading).

Nature of Organic Ion Exchange Polymers

Chemical Composition

Organic ion exchangers are made by polymerization of organic monomers into large molecules which are made insoluble by crosslinking with a polyfunctional monomer. The nature and the level (concentration) of

the crosslinking influences the elasticity, the dimensional stability or strength of the copolymer particle, and the available space surrounding the ionogenic or catalytic site within the solvent-swelled gel phase.

Many monomers have been transformed into insoluble ion exchangers by various polyfunctional monomers, but an unabridged listing of these will not be given here. Instead, this discussion will consider only those monomer systems most used.

The most prominent insoluble copolymer matrices for constructing organic ion exchangers are those derived by the free radical copolymerization of styrene with divinylbenzene. Other matrices that have been used and are presently used to a much lesser extent are those made by the condensation polymerization of phenol (including the other hydroxylated aromatic derivatives of phenol such as catechol, resorcinol, hydroquinone, etc.) with formaldehyde and the copolymer matrices made by the free radical polymerization of the acrylate and methacrylate monomers with divinylbenzene.

The functional groups that perform the catalytic work are attached to the preformed crosslinked polymeric matrix. A vast array of chemistry allows the attachment of many different functional groups for anchoring the catalytic agent. With the aromatic polymers, electrophilic substitution reactions provide the means of functional group attachment, and with the aliphatic acrylic and methacrylic resins, the carboxyl group provides the means of functional group attachment by nucleophilic substitution reactions. A plethora of chemistry is available to build a heterogeneous catalyst upon the polymeric matrices employed to make ion exchangers.

Much of the chemistry for designing effective catalysts built upon crosslinked polymers, however, has not been pursued to a fruitful outcome. Many of the special heterogeneous catalysts have been built upon crosslinked polymers with poor mass transport in the solvent systems necessary for effective chemical transformations and, therefore, have had inferior performance to the corresponding homogeneous catalysts. This inferior performance resulting from poor mass transport has partially quenched the commercial development of what could be excellent heterogeneous catalysts when built upon the properly designed structures of the crosslinked polymers. As a result, most of the commercial effort to use ion exchangers as catalysts has been in two areas – acid- and base-catalysed reactions. Solid acids and solid bases are the two major ion exchangers employed in water demineralization and purification and have been most explored as catalysts.

The strong acid ion exchangers are sulfonated polymers of styrene crosslinked with divinylbenzene.

The solid bases are copolymers of styrene and/or vinylpyridine crosslinked with divinylbenzene and functionalized to give either a quaternary ammonium hydroxide group or a tertiary amine group. Solid bases are also prepared from copolymers of the acrylate and methacrylate monomers by crosslinking with divinylbenzene followed by attachment of the amino group to the polymer via an amide linkage.

Physical Structure

The geometry of ion exchange particles as manufactured today is spherical. The bead diameters can be varied by the method of manufacture, but the standard size of commerce is a Gaussian distribution of beads ranging in diameter from 250 μm (60 mesh US Sieve Series) to about 1000 μm (18 mesh US Sieve Series). The condensation polymers of phenol with formaldehyde may still be supplied as irregularly shaped particles, but even these polymers can be made in spherical bead form, if desired. The spherical geometry arises from the method of manufacture which is by stirring a suspension polymerization of monomer droplets dispersed in an immiscible liquid. The immiscible liquid most used is water properly formulated to maintain droplet integrity throughout the transformation of monomer into polymer.

Recently a number of manufacturers of ion exchangers have developed technology for making monosized particles in which the range of size is very narrow with a uniformity coefficient of less than 1.12. Monosized particles may have an advantage in some catalytic applications if the ion exchanger being used is a gel resin. The monosized gel beads will have an advantage over a Gaussian distribution of beads if the average diffusional path length is shorter for the monosized beads than that for the Gaussian distribution. For macroporous polymers, the bead diameter has a very small impact upon the mass transport because the ingress and egress is through a continuous pore system rather than through a solvated polymer network as in a gel polymer.

Ion exchange beads have two internal polymer morphologies: one is a gel in which the network of polymer chains is continuous throughout the bead volume; the other is a macroporous structure in which the bead is constructed from small microgel particles tending towards spherical symmetry and packed together into clusters and arrays of clusters. The macroporous bead has both a continuous pore phase and a continuous gel phase, whereas the gel bead has only a continuous gel phase. Within the gel bead, there are no pores. Porosity develops only as the polymer chains are solvated by the reaction medium and become

solvent separated. Within the macroporous polymers, there are two subgroups: those with a small specific surface area (\bar{S}) less than about 400 to 500 m² mL⁻¹ and those with a large specific surface area greater than about 600 m² mL⁻¹.

The macroporous polymers with a small specific surface area have good accessibility into the core of the bead but the number of catalytic sites on the pore surface is insufficient to provide acceptable rates of catalysis. Consequently, the working phase in these beads is primarily the gel phase of the microgel. The macroporous polymers with a large specific surface area (\bar{S}) have sufficient catalytic sites on the internal pore surface to give acceptable rates of catalysis and are, therefore, true surface phase catalysts. Table 1 shows these relationships for a family of sulfonated macroporous polymers.

In the macroreticular synthesis of macroporous polymers, large surface areas are achieved only by increasing the level of crosslinking in the polymerizing monomer mixture. The microgel of the resulting polymer is so tightly crosslinked that it is impenetrable even to molecules as small as methylene dichloride (CH₂Cl₂). For effective catalysis, the surface phase must be the working arena since the gel phase is impenetrable and also not functionalized. Consequently, mass transport and catalytic effectiveness are influenced quite differently within these three physical structures by the following:

1. Level of crosslinking
2. Bead diameter
3. Solvating nature towards the polymer by the reaction medium
4. Size of the reactants and/or products.

Mass Transport: A Critical Element in Performance

With ion exchangers as with other heterogeneous catalysts, mass transport of reactants into the catalytic site and mass transport of products from the catalytic site can become totally rate controlling. A qualitative tabulation of these interacting relationships is provided in Table 2.

For estimating the suitability or design of a macroporous polymer for effective mass transport, the equation given below, derived from the studies of Halász and Martin, has been found very useful. The appropriate pore system for good mass transport can be selected by simply knowing the molecular weight of the expected product or the largest reactant molecule.

$$d_p = 5 d_M$$

$$d_M = 0.2457 (MW_M)^{0.588}$$

where: d_p = pore diameter in Å of the pore system at 50% of the total pore volume of the macroporous polymer; d_M = random coil diameter in Å of either the product molecule or the largest reactant molecule; MW_M = molecular weight of product or largest reactant.

Functional Groups – Catalytic Agents

The most studied catalytic functional group is the sulfonic acid group (–SO₃H) attached to styrene-divinylbenzene copolymers of both gel and macroporous morphologies. Many reactions catalysed by

^a Amberlyst XN-1008 is no longer marketed commercially. It has been replaced by Amberlyst 16 which has a similar specific surface area but is slightly more porous.

^b Amberlyst XN-1005 is no longer commercially available.

Table 2 Qualitative relationship between polymer morphology of ion exchanger and change in reaction system

<i>Polymer morphology</i>	<i>Change in the reaction system</i>	<i>Effect on the kinetics of catalysis</i>
Gel polymer	Increasing level of crosslinking from 2 to 12 wt.% divinylbenzene	Decreasing rate of reaction. Gel copolymers of styrene–divinylbenzene with greater than about 6% divinylbenzene perform poorly as catalysts even in good swelling solvents
	Increasing bead diameter from 250 to 1000 μm	Decreasing rate of reaction. In good solvating reaction medium, the smaller the bead diameter, the better the catalyst performance
	Poorly solvating reaction medium for catalyst	Ineffective catalysis at any particle diameter and any crosslinking level
	Increasing size of reactants and/or products	Decreasing effectiveness as a catalyst
Macroporous polymer with small specific surface area (\bar{S}) ($\bar{S} < 400\text{--}500\text{ m}^2\text{ mL}^{-1}$ bead)	Increasing level of crosslinking from 6 to 25 wt.% divinylbenzene	Moderate decline in catalytic effectiveness from compensating changes. As the crosslinking level increases, the \bar{S} increases and the microgel diameter decreases
	Increasing bead diameter from 250 to 1000 μm	For small to moderate sized molecules, almost no change in catalytic effectiveness
	Poorly solvating reaction medium for catalyst	Very small impact on catalytic performance
	Increasing size of reactants and/or products	Provided the pore system is sufficient for ingress of reactants and egress of products, only a moderate decline in effectiveness
Macroporous polymer with large specific surface area (\bar{S}) ($\bar{S} > 600\text{ m}^2\text{ mL}^{-1}$ bead)	Increasing level of crosslinking from 60 to 100 wt.% divinylbenzene	Increasing catalytic effectiveness, provided pore dimensions remain large enough to accommodate entrance of reactants and exit of products. As level of DVB increases, the surface area increases
	Increasing bead diameter from 250 to 1000 μm	Little or no impact on catalytic effectiveness
	Poorly solvating reaction medium for catalyst	No impact upon catalytic effectiveness
	Increasing size of reactants and/or products	No impact upon catalytic effectiveness provided pore system allows influx of reactants and efflux of products

homogeneous strong acids have been examined for effective catalysis by strong acid ion exchangers because of their lack of corrosiveness and their ease of separation from the reaction liquor by filtration (Table 3). Strong acid resins with crosslinking by divinylbenzene of 8 wt.% or less work well only where the reaction medium is very polar (water, dimethylformamide, N-methylpyrrolidinone or dimethyl sulfoxide) and the reactants or resulting products are small ($\text{MW} < 250\text{ Da}$).

Strong acid macroporous polymers work well in essentially all reaction media, especially the large specific surface area, strong acid macroporous polymers where the surface phase is the catalytic arena. Here solvation of the gel phase is unimportant. The surface phase sulfonic acid groups, however, are not as powerful in protonating reactants as those buried in the gel phase – the surface sulfonic acid moiety is a weaker acid than those within the gel. By placing two sulfonic acid groups on each surface ring, by

sulfonation with fuming sulfuric acid, both the acid strength and the thermal stability are increased. Sulfonated aromatic polymers with the sulfonic acid group attached directly to the aromatic ring begin to desulfonate at about 120°C , since sulfonation is acid catalysed and reversible. By attaching an electron withdrawing group, such as $-\text{SO}_2-$, $-\text{SO}_3\text{H}$, Cl, Br, F, etc., to the aromatic ring, in addition to the sulfonic acid group, the thermal stability of the strong acid resin is boosted to about 150°C .

Ion exchangers have their functional groups anchored in space relative to each other and the neighbouring groups can be used to enhance the rates of reactions of appropriately structured molecules. As an example of this effect, the rate of hydrolysis of olefinic esters is greatly enhanced by loading silver cations on to a portion of the sulfonic acid groups. At 50% loading of the cation exchanger with silver cations, the maximum rate of hydrolysis of allyl acetate is observed even though the concentration of acid

sites is halved. The silver ion with its propensity to complex with double bonds pulls into the resin phase a higher concentration of allyl acetate, thereby increasing the rate of hydrolysis over that of the strong acid resin without silver cations. This is a polymeric matrix effect which is not possible with a homogeneous catalyst. Polymeric matrix effects are an added advantage of solid phase over liquid phase catalysts for enhancing the catalytic effectiveness of ion exchangers.

Anion exchangers are the second most studied group of solid phase catalysts. The catalytic agents that are attached to the polymeric matrices are quaternary ammonium and tertiary amine groups. The positively charged nitrogen of the quaternary ammonium group is effective in catalysing some reactions, but most often it is the associated anion that is varied to achieve an effective catalytic agent. The positively charged nitrogen of the quaternary group is effective in catalysing epoxide addition reactions, as one example. Base catalysis is carried out with either the quaternary ammonium hydroxide or the tertiary amine group. For reactions

whose products are sensitive to the base strength, a less powerful basic anion such as carbonate or acetate can be employed when the quaternary ammonium agent is the catalyst. The quaternary ammonium resin in the hydroxide form begins to decompose when used above 60°C. Other anionic forms are stable to about 150°C. The tertiary amine resins are thermally stable to about 150°C.

Phase transfer catalysis is accomplished by anion exchangers with any one of a number of appropriate nucleophilic anions associated with the quaternary ammonium group. The appropriateness of the nucleophilic anion is controlled by the nature of the chemical reaction undergoing catalysis. Phase transfer catalysts can also be designed by attaching a quaternary phosphonium group to the polymeric matrix in place of the quaternary ammonium group. Spacer arms that move the onium group further from the crosslinked polymer backbone enhance catalytic activity in phase transfer catalysis.

Crosslinked styrene-divinylbenzene copolymers have been and continue to be actively investigated as solid supports to heterogenize homogeneous catalytic agents. These solid phase catalysts have transition metals and noble metals anchored to the solid polymeric matrix through appropriate ligands. In heterogeneous form, they promote the same chemical reactions as in solution, albeit with the imposed mass transport limitations of the solid support.

Development of Ion Exchange Concept, Materials and Methods

The main stages in the development of ion exchange are shown in Table 1 and 2. Ion exchange gradually became an important separation method in water treatment, waste water purification, analytical chemistry, medicine, the food industry and many other areas of application.

The first systematic studies of ion exchange occurring in natural inorganic materials were performed during the period 1850–80, clays, sands and zeolites became objects of investigation and it was shown that soil treated with ammonium salts absorbs these ions, releasing an equivalent amount of calcium ions. Later, some natural materials found application for purification of water as well as for other purposes. At that time, the evidence for existence of ions in solution had not yet been elucidated and the concept of a double electric layer had not yet been proposed. Despite this the stoichiometry of ion exchange and its connection with aluminosilicates present in the soil were established. It was demonstrated that the degree of exchange increased up to a limiting value with the

increase of concentration of salt solution, while the influence of temperature on ion exchange was shown to be less significant.

At the beginning of the twentieth century complementary investigations in the areas of synthesis and application of ion exchangers took place. Industrial production of synthetic amorphous aluminosilicate ion exchange materials was started. These materials (permutites) were used for water softening and in the treatment of sugar syrups. In the first artificial sodium aluminosilicates a substitution of sodium to calcium occurred, but the ion exchanger could be regenerated in a column by treatment with saturated sodium chloride solution.

Ion exchange materials can also be obtained by oxidation and sulfonation of coals. Some types of charcoal, soft and hard brown coals, are suitable for this purpose. They can be converted into cation exchangers after treatment with fuming sulfuric acid. As a result, sulfonic and carboxylic groups (resulting from oxidation) are introduced into the coal structure, playing the role of fixed ions. Furthermore, the coal is transformed to a gel due to polycondensation reactions. The total exchange capacity of such materials is about 1.5 meq g^{-1} .

Organic Ion Exchange Materials

Later, the ion exchange properties of some organic materials were discovered, which led to the creation

Table 1 Principal practical achievements in the field of ion exchange

Year	Milestone
1850–52	Discovery of ion exchange phenomenon in soil (Thompson, Way and Roy)
1903	The first synthetic inorganic ion exchanger (Harms, Rümpler, Gans)
1935	The first ion exchange resin possessing high capacity (Adams and Holmes)
1944	Development of ion exchange resin synthesis by means of copolymerization (d'Alelio)
1947	Synthesis of zeolites (Barrer)
1950	Synthesis of ion exchange membranes (Wyllie, Sollner)
1958	Synthesis of inorganic ion exchanger based on zirconium phosphate (Amphlett)
1964	Synthesis of the first crystalline zirconium phosphate of α -type structure (Clearfield and Stynes)
1975–79	Development of ion chromatography (Small, Gjerde)
1980–present	New layered materials of α - and γ -types, organic ion exchangers; improvement of ion exchange chromatography method

Table 2 Important theoretical advances, elucidating the essence of ion exchange

<i>Year</i>	<i>Milestone</i>
1879	Helmholtz theory of electrical double layer
1911	Donnan theory of membrane equilibria
1950s	Statistical ion exchange models of Gregor, Kachalsky, Harris and Rice
1958	First edition of Helfferich's monograph devoted to ion exchange was published
1940s (2nd half)–1960s	Theories of ion exchange dynamics are developed
1960s (2nd half)–present	Theoretical models and description of new crystalline layered materials possessing ion exchange properties
1980–present	Theoretical background of ion exchange chromatography

of an ion exchange resin by Adams and Holmes. These new materials were characterized by their high capacity ($5\text{--}10\text{ meq g}^{-1}$) relative to inorganic ion exchangers. Resins were obtained by polycondensation of phenols or amines with formaldehyde, and their large-scale production began. Owing to their high degree of cross-linking the polymers had negligible solubility. The resins were hydrophilic due to the presence of ionic groups as an inseparable part of the polymer matrix: for example, for anion exchange resins amino groups inside the matrix were balanced by an equivalent quantity of anions. For cation exchangers phenolic, sulfoxylic, carboxylic or phosphonate or phosphinato groups were present inside the matrix, balanced by an equivalent quantity of cations.

A discovery by d'Alelio had great industrial significance. He invented a method of synthesis of ion exchangers based on styrene–divinylbenzene copolymers. This invention was anticipated by Staudinger's synthesis of reticular polystyrene. The first cation exchanger of this type was obtained in 1944, followed in 1948 by an equivalent anion exchanger. These resins possess high chemical and mechanical stability; their distinguishable feature is

a certain degree of control over the synthetic process. Moreover, such materials were characterized by high exchange capacity and working exchange rate. Different fixed ions can be introduced into the styrene–divinylbenzene matrix, offering a possibility to obtain resins with different cross-linking numbers and swelling behaviour. All these properties make this kind of synthetic resin of major practical significance (Table 3).

In the area of water treatment ion exchange techniques occupy a leading position worldwide and due to their increasing importance they are under continuous development. In 1951 Reents was the first to apply a mixed layer of anion and cation exchangers for the ultra-purification of water.

Emergence of cross-linked polymer electrolyte–ion exchange resins has allowed a new approach to the solution of problems of analytical and preparative chemistry: purification and separation of compounds possessing similar chemical properties. However, water treatment and waste water purification remain the main areas of application of ion exchange resins. Here exchangers capable of being universal absorbents for a wide variety of ions are mainly needed. Parallel to investigations aimed at enhancing sorption

Table 3 Main fields of application of ion exchange resins

<i>Resin type</i>	<i>Matrix type</i>	<i>Type of fixed groups</i>	<i>Application fields</i>
Strongly acidic cation exchange resins	Gel Macroreticular	Sulfonic	Water treatment; separation of rare earth elements; separation of amino acids, etc.
Weakly acidic cation exchange resins		Carboxylic	Decarbonizing of industrial water, water softening and deionization
	Gel Macroreticular		Purification of antibiotics, copper and nickel recovery
Strongly basic anion exchange resins	Gel Macroreticular	Quaternary ammonium	Different water conditioning processes; elimination of organic compounds with high molecular weight (macroreticular)
Weakly basic anion exchange resins	Gel Macroreticular	Tertiary amine or polyamine	Industrial water treatment; decolorization of sugar syrups (macroreticular)

capacity, improving the exchange kinetics, thermal stability, mechanical properties and chemical resistance, there has been a considerable development of selective ion exchangers. This requirement arose in the 1950s in connection with both the analytical problem of direct selective determination of elements in a complex mixture and the problem of extraction of metals from technological solutions during complex ore processing. The selectivity of ion exchangers is determined by two factors. The first consists of an exact correlation between the dimension of the sorbent's pores and the radius of the hydrated ion to be absorbed. The second factor is related to the formation of a coordination bond supplementary to an ionic one between the ion and the functional groups within the matrix.

Besides development of polymeric acids and bases of different strengths, ion exchangers containing functional groups able to form chelate complexes with specific ions have also been obtained. This class of ion exchangers is characterized by high ion exchange constants and high selectivity owing to donor-acceptor interaction between adsorbent and adsorbate. In 1940, Skogseid made a macromolecular ion exchanger selective towards potassium, containing moieties analogous to dipicrylamine. Iron, uranium and rare-earth elements readily form complexes with oxygen-containing ligands. Several early transition metals like cobalt, nickel and copper give rise to stable amino complexes. Thus, anion exchangers containing amino groups (preferably those of primary amines) are selective for the latter group of elements, while exchangers containing phenolic groups are suitable for iron. Resins with carboxylic and phosphonic groups are suitable for uranium and rare-earth metals.

However, some researchers consider the ion exchange procedure of water treatment a kind of 'ecological boomerang', bearing in mind the fact that wastewater after ion exchange still contains many mineral compounds. Regeneration solutions contain them in quantities greater by an order of magnitude than the level of contaminants to be extracted. Ion exchange membranes avoid this disadvantage. The increase of mass of compounds in wastewater with respect to the quantity of extracted substances does not take place during membrane purification, providing a significant advantage for this method, when compared to distillation or sorption on ion exchangers. In 1950, the first samples of heterogeneous membranes were obtained by Wyllie and Patnode based on commercial ion exchangers reinforced by inert polymer fibres in order to provide high mechanical stability. In 1952, Manecke and Sollner reported the first homogeneous membrane, and in 1957 Gregor made the

first inter-polymer membranes, where the ion-exchange and binder components are linked to each other by chemical bonds. Ultra-pure water cannot be obtained by the sole use of ion exchange membranes: nowadays one has to assemble a combination of separation methods such as filtration, microfiltration, ultrafiltration, reverse osmosis, electrodialysis with ion exchange membranes and a mono-layer of granulated ion exchange resin, and electrodialysis with ion exchange membranes filling the inter-membrane space with a mixed layer of granulated ion exchange resins.

Inorganic Ion Exchangers and Application of Inorganic Layered Materials

A reawakening of interest in inorganic ion exchangers was connected with the search for materials which can withstand high temperature, ionizing radiation and some aggressive chemicals. In 1943, Russel *et al.* discovered that insoluble zirconium phosphate is suitable for the separation of uranium and plutonium from nuclear fission products. Thus, a new class of inorganic ion exchangers was synthesized on the basis of group 4 elements, mainly of titanium and zirconium. Various kinds of functional groups can be attached to the polymer chains consisting of Ti or Zr atoms bonded to oxygen, producing different types of ion exchangers. It is a well-known fact that zirconium readily forms chains:

in solution. The behaviour of titanium is analogous. The most intense polymerization occurs in a range of pH values close to that of the hydroxide sedimentation. A polymer containing zirconyl groups together with residues of acid is obtained by addition of salt or acid to a zirconium (or titanium) salt solution. If the acid is polyprotic, then one obtains a cation exchanger containing an exchange site like:

The first material of this kind was zirconium phosphate obtained by Amphlett in 1958. It possessed a capacity of 1 meq g⁻¹ at pH 3, and 5 meq g⁻¹ at pH 11. Amorphous inorganic sorbents had a great advantage over organic resins owing to their ease of preparation.

In 1947 Barrer realized a synthesis of zeolite for the first time. He became a founder of zeolite chemistry, studying synthesis, structure, sorption and ion exchange properties of this new class of materials.

In 1964, Clearfield and Stynes synthesized the first crystalline zirconium phosphate and established its layered α -type structure $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, usually referred to in the literature as $\alpha\text{-ZrP}$. In 1968, the same authors reported the first γ -type zirconium phosphate, referred to as $\gamma\text{-ZrP}$. Since 1975, some organic derivatives of the latter modification have been synthesized by Yamanaka *et al.* Further development of this class of inorganic ion exchanger by Alberti *et al.* (1978) resulted in M(IV) phosphonates and organic phosphates with a layered structure of zirconium bis-monohydrogen phosphate ($\alpha\text{-ZrP}$). Some years after the first inorgano-organic sorbent was reported, Dines and Griffith described the synthesis of diphosphonates of general formula $\text{M(IV)}(\text{O}_3\text{P-R-PO}_3)$. A series of covalently pillared diphosphonates with a regular interlayer microporosity was subsequently obtained. As far as $\gamma\text{-ZrP}$ ($\text{ZrPO}_4(\text{H}_2\text{PO}_4) \cdot \text{H}_2\text{O}$) is concerned, a wide variety of layered and pillared M(IV) phosphonates were obtained in the period 1987–1990, since their structure depends on the starting material and on the nature of the $\text{O}_2\text{PRR}'$ group that replaced $\text{O}_2\text{P}(\text{OH})_2$.

Ion Exchange Chromatography

High performance in the separation of organic substances by liquid chromatography had already been achieved by the 1970s, while techniques of chromatographic separation of inorganic ions were developed to a lesser extent. In 1971, the first papers dealing with automatic spectrophotometric detection of metal ions separated by ion exchange chromatography on cation exchange resins appeared. Similarly, anions were separated on anion exchange resins. Conductometric detection was established by Small *et al.* in 1975 and Gjerde *et al.* in 1979. Finally it is necessary to mention ion exclusion chromatography applied to separate sugars and carbonic acids with an ion exchange column, but without any ion exchange interaction.

Development of Theoretical Background in the Field of Ion Exchange

Helmholtz developed the theory of the double electric layer in 1879, and this had a fundamental significance for the explanation of many phenomena related to ion exchange. According to his classic theory, the double layer consists of two electric layers, analogous

to the plates of an electric capacitor. The concept was later modified, as it had been proven that a double layer is formed at the interface between a solid phase and a solution. It consists of an immobile inner layer and a diffuse outer layer. Charge separation in this type of a system is of the order of molecular dimensions. As a result, the solid phase surface acquires an electric charge (positive or negative), while the counterions are distributed along the interface. These ions form a virtual outer plate of the diffuse layer. In fact, there is no interface but a dynamic equilibrium exists between the ions in the diffuse layer and those of the environment (the bulk solution). The existing equilibrium is disturbed upon changes in either pH or concentration of ions in the bulk solution. In this case new ions enter the diffuse layer, substituting ones already there and establishing a new ion exchange equilibrium.

The influence of valence, hydration and ion dimensions on the degree of ion exchange transformations has been established and ion selectivity series were composed by Wiegner for ion retention on aluminosilicate sorbents:

Mattson demonstrated in 1927 that aluminosilicates enriched in silica gave an increase in cation exchange capacity. Jaeger demonstrated that at higher concentrations, as well as in mixed organo-aqueous solutions, the values of the exchange potentials of ions with the same valence could be quite close, with possible inversion of the selectivity series.

Selectivity, i.e. preferable absorption of one of the counterions, is an important property of ion exchangers. Hence, the ion exchanger becomes enriched in counterions which possess small dimensions in the solvated state or which are able to enter into specific interactions with the fixed ions or with the matrix. The isotherm of ion exchange is a graphical representation of the dependence of an equivalent fraction of the counterion A in the ion exchanger, versus its equivalent fraction in solution.

In 1939 Nikolskii demonstrated that the law of mass action could be applied successfully to ion exchange:

$$(\gamma_1^{1/Z_1})/(\gamma_2^{1/Z_2}) = K(a_1^{1/Z_1})/(a_2^{1/Z_2})$$

where γ_1 and γ_2 are the quantities of ions absorbed by the resin (meq); Z_1 and Z_2 are charges of these ions in solution; a_1 and a_2 are activities of the above ions in the solution and K is the ion exchange constant.

In 1935 Kielland introduced activity coefficients for the ion exchanger phase in order to estimate deviations of ion exchange equilibria from a simple form of the law of mass action. The most clear thermodynamic approach to these equilibria was provided by Gaines and Thomas in 1953, which was not connected to model concepts.

A physical model of ion exchange processes has been gradually formed together with the accumulation of empirical data. For example, the theory of membrane equilibria created by Donnan in 1911 promoted a breakthrough after its application to ion exchange processes. The essence of Donnan theory can be briefly described as follows. An electrolyte RNa is supposed to be on one side of a membrane, and an NaCl solution on the other side. Since the membrane is not permeable for R^- ions, only sodium and chloride ion redistribution will take place in the system. However, in the above case the diffusion process is unable to equalize concentrations of all ions from both sides of the membrane. For ion exchange equilibria, an interface between liquid and solid phases is considered as a membrane, while a colloidal particle bearing the exchangeable ion is assumed to be a non-diffusing ion.

In the early 1950s, Gregor proposed an osmotic theory of exchange. According to this model, the matrix of ion exchange resin is expanded upon swelling, and thus applies pressure to the liquid inside the pores. In such a case the equilibrium is determined by a difference in the osmotic pressure between the external solution and that of the liquid inside the pores together with the elastic forces of the matrix. However, Gregor's model does not consider the formation of ion pairs, and hence does not explain selective adsorption; moreover, its accuracy is not sufficient to describe exchange in dilute solutions, which are typical for ion exchange processes.

Some years later another model of ion exchange appeared, built on a molecular background rather than the macroscopic Gregor model. The model of Kachalsky (mid-1950s) presumes that the energy of electrostatic interaction which imparts changes in free energy of the system is uniformly distributed over the polymer chain between the ionogenic groups. The model describes the resin as a linear polyelectrolyte and provides an accurate description of ion exchangers with a small number of cross-linking bonds.

A similar approach was used in the model developed by Harris and Rice at about the same time. It also uses a molecular level approach and the concept of linear polyelectrolytes, but the authors concentrated on interactions of neighbouring functional groups both in the same and in the adjacent polymer

chains, taking into account the regular distribution of fixed ions in the ion exchange resin phase. Another distinctive feature of this model is that it considers ion pair formation between the fixed ions and counterions.

Pepper has studied swelling of different absolutely dry resins in water and demonstrated that the total volume of the system undergoes shrinkage at the first step and then remains unaltered. Thus initially, the primary hydration shell is formed which consists of the so-called 'fixed' water, possessing specific properties. The water absorbed afterwards is called 'free' water and behaves like ordinary loosely bound water. The degree of swelling depends on the structure and cross-linking of the particular resin. Inorganic ion exchangers usually have a rigid crystal structure and their swelling is insignificant; layered ion exchangers undergo intralaminar swelling.

Ion exchange interactions occur at different rates in heterogeneous media; therefore studies dealing with ion exchange kinetics are of great importance. In 1947, Boyd and co-workers showed that the exchange rate is determined either by the diffusion rate inside the resin bed (gel diffusion) or by the diffusion in the layer of liquid surrounding the bed (film diffusion). When the rates of gel and film diffusions are comparable, both components determine the exchange rate. Determination of the mechanism and the limiting stage of the ion exchange process presents a rather difficult problem, because the kinetics simultaneously depend on a number of parameters, such as the concentration of adsorbate in solution, the nature of the ionic species, the type and granular composition of the ion exchanger and the relative migration rate of the interacting phases. The limiting stage of ion exchange can be approximately estimated as follows:

for gel diffusion:

$$(c\bar{D}\delta)/(cDr_0) \cdot (5 + 2K_{A/B}) \ll 1$$

for film diffusion:

$$(c\bar{D}\delta)/(cDr_0) \cdot (5 + 2K_{A/B}) \gg 1$$

and in case of mixed diffusion:

$$(c\bar{D}\delta)/(cDr_0) \cdot (5 + 2K_{A/B}) \approx 1$$

where $\bar{c} = z_i \bar{c}_i$, $c = \sum z_j c_j$ are total concentrations of exchanging ions in the solid and liquid phases

respectively; \bar{D} and D are ionic diffusion coefficients in the solid and liquid phases, respectively; δ is the thickness of the diffusion interlayer; r_0 is the radius of the ion exchanger bed; and $K_{A/B} = \bar{c}_A c_B / c_A \bar{c}_B$ is the separation coefficient for both sorts of counterions in the equilibrium state: the counterion A is present initially inside the bed, while the counterion B is initially in solution.

An equivalent exchange takes place under the following condition:

$$z_R \bar{c}_R = \sum_i^n z_{Ai} \bar{c}_{Ai}$$

where \bar{c}_R is the concentration of fixed groups inside the bed, \bar{c}_{Ai} is the concentration of i -th counterion. This is only an approximation, applicable to ion exchangers of high capacity treated with relatively dilute aqueous solutions. In all other cases, the ion exchanger absorbs a significantly higher quantity of ions than is needed for equivalence, i.e. a super-equivalent exchange occurs. An excess of counterions penetrates into the exchanger bed accompanied by a quantity of co-ions, necessary to compensate the electric charge of the former, in order to preserve a condition of electroneutrality of the bed:

$$z_R \bar{c}_R + \sum_{j=1}^n z_{Xj} c_{Xj} = \sum_{i=1}^m z_{Ai} \bar{c}_{Ai}$$

The higher the concentration of external solution, the greater is the contribution of super-equivalent exchange. Even for zeolites and highly cross-linked resins it becomes apparent at concentrations of external solution of about 0.1 N and higher. For scarcely reticulated, macroporous, highly swelling or weakly charged ion exchange resins the super-equivalent exchange has a much more pronounced effect and it becomes distinguishable at considerably lower concentrations.

A sorption without ion exchange is usually named Donnan absorption of electrolyte, because the thermodynamic description of the process is principally the same both for the system 'ion exchanger-solution' and for systems with a real semipermeable membrane as an interface separating phases in Donnan theory. However, the latter postulates that the dissociation in both phases is complete. Another situation is observed when the exchange occurs between the bed and weakly dissociated electrolyte or when ionogenic groups on the former are weakly dissociated. In that case, one deals with sorption of fragments of undissociated molecules and ion pairs and the exchange cannot be described in terms of Donnan theory. The

concept of 'super-equivalent exchange' includes the exchange of ions, absorption of electrolyte molecules without ion exchange, and other processes which could be characterized as between the above two cases.

Recent Progress in Ion Exchange

In recent years extensive research has been carried out on new crystalline inorganic and inorgano-organic layered compounds which possess ion exchange properties. Each layer in their structure can be considered as a planar macromolecule, while the substance as a whole is assumed to be a molecular crystal formed by these planar macromolecules. A reversible process of intercalation between the layers occurs due to interactions of guest species with active sites on the surface of the layer (lamella). However, the layers are unable to move spontaneously in a direction perpendicular to the plane. This is due to a certain rigidity of layers that plays an important role in intercalation reaction mechanism and energetics. Like other ion exchange materials, the charged layered solids may be strong, medium or weak cationic (or anionic).

The exchange of protons of α -ZrP phase for Li^+ , Na^+ and Ca^{2+} occurs rapidly in acidic solutions, while H^+ exchange for larger or strongly hydrated cations like NH_4^+ , Rb^+ , Cs^+ , Ba^{2+} , Mg^{2+} , Cu^{2+} and Cr^{3+} is quite slow at room temperature due to the high activation energies of interlayer expansion. Exchange can be facilitated in materials with large interlayer distances like α -Zr(HPO_4)(NaPO_4) \cdot $5\text{H}_2\text{O}$ ($d = 11.8 \text{ \AA}$) or in intercalation compounds with ethanol or alkylamines. The compounds that can be protonated are preferably used as guest species. For example, an amino derivative of cyclodextrin has been used for intercalation, increasing the interplanar distance in α -ZrP up to $d = 35.6 \text{ \AA}$. These distances for other guest species are; 14.2 \AA for ethanol, 20.4 \AA with benzimidazole, 22.8 \AA with 1-hexylamine and 23.1 \AA with lysine. The layered compounds under discussion can swell upon introduction of water or other solvents into the interlayer space. Sometimes the process leads to delamination, i.e. destruction of the crystal into separate lamellae. Withdrawal of the solvent results in reaggregation of the lamellae in thin films or membranes. Inorgano-organic derivatives, phosphonates of layered α -structure, can be obtained by introducing the corresponding acid $\text{H}_2\text{O}_3\text{PR}$ (where $\text{R} = -\text{CH}_3$, $-\text{C}_6\text{H}_5$, $-\text{O}(\text{CH}_2)_n\text{CH}_3$ etc.) into the reaction, instead of H_3PO_4 . It is also possible to synthesize those compounds by substitution of existing OH groups in the α -ZrP structure by R or OR. Another interesting group of compounds is

covalently pillared zirconium diphosphonates of general formula $M^{IV}(O_3P-R-PO_3)$. If the R group is small, then a low degree of interlayer microporosity is observed, while for pillared compounds containing fragments of 3,3(5,5)-tetramethylbiphenyldiphosphonic acid the value of interlayer porosity is raised to $375\text{ m}^2\text{ g}^{-1}$ (an average pore size of 5 \AA). Inorgano-organic derivatives have also been obtained for γ -ZrP by substitution of the interlayer $O_2P(OH)_2$ groups for O_2PRR' . Pillared phases of γ -ZrP with, for example, biphenylphosphonate groups have a volume of micropores of $320\text{ m}^2\text{ g}^{-1}$ and an average size of 5.8 \AA .

A limited number of inorganic anion exchangers is known. Layered double hydroxides (or hydrotalcite-like anionic clays) can exchange a large number of inorganic and organic anions, while layered $ZrPO_4Cl$ can selectively replace chloride anions with other monodentate anionic ligands.

Currently, ion exchange is of extreme importance for processing of irradiated nuclear fuel and treatment of spent fuel elements of nuclear power stations, where it is often combined with other techniques, e.g. extraction. The processes of sorption play an important role in deactivation of nuclear industry wastes and in purification of cooling water from nuclear reactors. Different kinds of ion exchangers are widely used for the clean-up of the world's worst nuclear accident at Chernobyl. For example, Strelko *et al.* are carrying out both research and application of highly selective inorganic granulated ion exchangers for elimination of radioactive isotopes from drinking water, milk, etc. Ion exchange is extensively used in medicine for haemosorption (or haemoperfusion) – the method of blood purification from toxic compounds by direct contact of the sorbent with the patient's blood. This method was applied for the first time by Muirhead and Reid in 1948; they directed the blood flow through a mixture of cation and anion exchangers taken in a ratio of 9:1. Haemosorption can be applied alone or in combinations with haemodialysis (when the toxins are distributed between two liquid phases, separated by a semipermeable membrane). The ion exchangers are used to regenerate dialysate from the artificial kidney apparatus. Further improvement of the haemosorption method is connected with the necessity to resolve problems of selective blood purification, as well as the problem of better sorbent compatibility with biological fluids. Another possible medical application of ion exchangers consists of the creation of drugs and pharmaceuticals with prolonged activity, offering the possibility to release an active component inside the patient's body over time and maintaining its necessary concentration.

A nontraditional application of ion exchangers in nonpolar organic media is the ultra-purification of organometallic compounds used as precursors in chemical vapour deposition. These precursors are widely utilized for synthesizing materials possessing valuable properties for micro-, opto- and acousto-electronics, and protective and optical coatings. The organometallics in question react readily with atmospheric oxygen and moisture, while at the same the requirements on their purity are quite rigorous (less than $1 \times 10^{-3}\%$ of the sum of contaminants). The above requirements can be met by treatment with a sorbent composition containing inorganic ion exchangers based on titanium and zirconium phosphates, thus replacing energy-intensive and expensive traditional methods (sublimation or distillation).

Future Developments

Undoubtedly, the future development of ion exchange as a method of separation will be directed towards ecological and biotechnological problems. The development of society parallel to scientific and technical progress will promote greater regard for natural resources. Hence, particular attention will be drawn to the application of renewable technologies and closed technological cycles including ion exchange stages or applying ion exchange materials mainly in the area of water treatment and wastewater purification, as well as in several other fields. Certainly, the use of ion exchangers in medicine will increase.

New, advanced ion exchange materials possessing desirable properties will be obtained by targeted synthesis; computer modelling and simulations as well as molecular design will be increasingly applied.

The specificity and selectivity of ion exchange will grow; i.e., the most suitable materials from the viewpoint of their origin, matrix type, the type of ionogenic groups etc. will increasingly be applied for specific cases.

The phenomenon of ion exchange discovered a century and a half ago, as well as processes established on the basis of it, are still in a process of dynamic development. The potential of ion exchange both in practical applications and from the elaboration of theoretical concepts related to ion exchange is not yet complete.

Summary

In the first part of this chapter, the origins of ion exchange in inorganic materials are discussed in relation to the structure of the exchanger. Thereafter, the various types of inorganic ion exchangers are introduced and categorized according to their ion exchange properties. Descriptions of particular materials follow, with special emphasis on some structure-specific and composition-specific ion exchange properties. The materials which are discussed include zeolites and zeolite-like materials, clays and other layered materials, zirconium phosphates, heteropolyoxometalates and hydrous oxides.

Types of Ion Exchange Sites in Inorganic Materials and their Origin

For the purposes of this chapter, ion exchange interactions will be defined as those involving the interchange of positively or negatively charged species (atomic or molecular) at an ion exchange site.

There are two types of chemical species which constitute the vast majority of ion exchange sites in inorganic materials:

1. structure-terminating, covalently bonded groups such as -OH
2. charge-compensating groups, electrostatically associated with, and not covalently bonded to, a charged moiety

Type 1 sites, illustrated in **Figure 1A**, are responsible for the ion exchange properties of materials such as hydrous oxides and single-layer clays. All oxidic materials have these sites to some degree, at the surfaces of particles or crystals or at defect sites within the structure. Ion exchange reactions involving these types of sites may be regarded as chemical reactions, which may display amphoteric nature.

Type 2 sites, illustrated in **Figure 1B**, are responsible for most of the ion exchange capacity of zeolites, double-layer clays and zirconium phosphates. These sites arise in structures possessing, for instance, charged layers or charged porous frameworks. The exchangeable ions are present to retain overall electroneutrality. When materials such as zeolites are concerned, a mixture of Type 1 and Type 2 sites is available, although Type 2 sites will usually greatly outnumber Type 1 sites, and the latter are often ignored. Exchange interactions involving Type 2 sites are physical in nature, as chemical bonds are neither made nor broken.

Types of Inorganic Ion Exchange Material

An important distinction between ion exchange materials is whether they exhibit capacity for cations, anions, or both. Cation exchangers, and in particular zeolites, clays and zirconium phosphates, are the most common and best understood of the ion exchangers. Anion exchangers are also important but

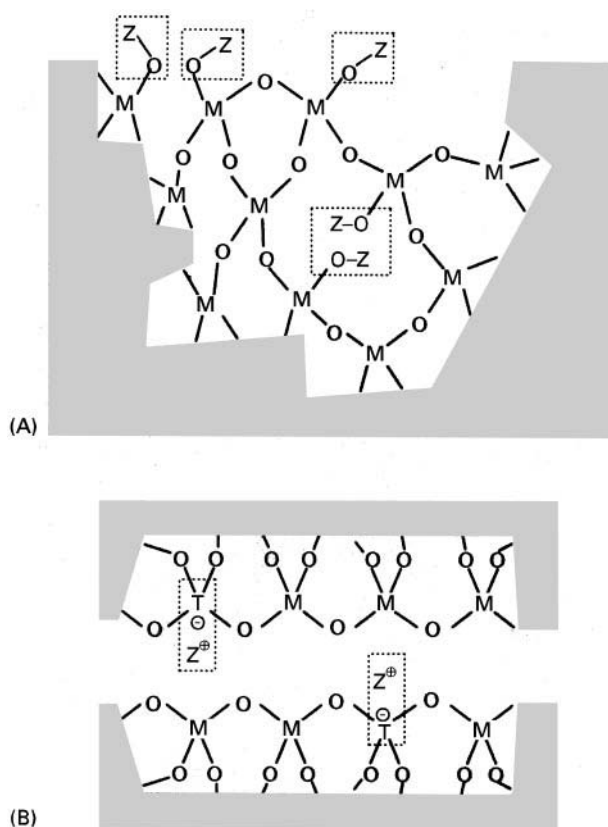

Figure 1 The two major types of ion exchange site. (A) Type 1, structure-terminating and defect groups; (B) Type 2, charge-compensating groups. M is an oxide-forming metal with oxidation state 4; T is an oxide-forming metal with oxidation state 3. The regions enclosed in dotted lines are those giving rise to ion exchange where Z^+ (or $Z-O^-$) is exchangeable. Shaded areas represent a continuation of the oxidic network.

the exchange of anions is often not fully reversible, thus the exchangers cannot be easily regenerated and the reactions are more difficult to treat thermodynamically. Multiply charged anions, in particular, may be held tenaciously by the exchanger. Examples of anion exchangers are certain clays such as hydroxy double salts (e.g. $[\text{CuNi}(\text{OH})_3]\text{Cl}$) and layered double hydroxides (e.g. hydrotalcite, $\text{Mg}_6\text{Al}_2(\text{OH})_{16}(\text{CO}_3) \cdot 4\text{H}_2\text{O}$). Amphoteric ion exchangers possess predominantly Type 1 exchange sites, e.g. hydrous oxides.

While ion exchange properties may be exhibited by both amorphous and crystalline solids, studies of the ion exchange properties of amorphous solids are often hampered by difficulties in preparing materials reproducibly and the difficulties in characterizing them fully. With crystalline materials, however, reproducible preparations can be easily verified and well-defined structural data aids in the interpretation of the results of ion exchange experiments.

Most crystalline inorganic ion exchangers are porous. This porosity may arise through the presence of void space between the layers in clay materials and layered double hydroxides, or through the intrinsic microporosity present in zeolitic materials. Many of the layered materials have the versatility to (reversibly) change their interlayer spacing and hence the size of the voids, which allows the ion exchange properties to be adjusted. The more rigid zeolite structures give rise to exchange reactions which may show extremely high selectivity to certain cations, or perform ion sieving.

Zeolites

Zeolites are microporous crystalline aluminosilicate minerals which occur naturally and may be synthesized easily in the laboratory. An introduction to the structures and properties of zeolites is given in the article by Dyer. Zeolites are used on a large scale as ion exchangers in many fields; most notable are their use as 'builders' or water softeners for laundry detergents, and their use in the decontamination of various types of waste streams. Typical applications of zeolites as ion exchangers are given in Table 1. Additionally, the ion exchange capability of zeolites can be used as a tool to modify their catalytic and sorptive properties. Some attention will be paid to structural parameters which influence the ion exchange properties of zeolites in the following paragraphs.

Besides the conditions under which an ion exchange reaction is performed, a number of factors may influence the ion exchange properties of zeolites, including:

- the structure of the zeolite, particularly the diameters of the windows allowing access to the pores and cavities
- the location of the ion exchange sites; different cation environments lead to different ion exchange properties. The number of charge-balancing cations required for an electroneutral material is often less than the number of available ion exchange sites, thus partial occupancy of sites is common. Some of the possible cation positions in zeolites A and X (two of the most widely used synthetic zeolite ion exchangers) are indicated in Figure 2
- the composition of the zeolite framework; varying the Si:Al ratio or changing the framework substituent elements may change, for example, the density of exchange sites, the electric field strength or the hydrophobicity of the sample as a whole

Table 1 Principal applications of zeolites as ion exchangers

<i>Application</i>	<i>Type of zeolite frequently used</i>	<i>Ion exchange process</i>
Detergent building	A (synthetic) MAP (synthetic) X (synthetic)	Removal of Ca^{2+} and Mg^{2+} from solution
Wastewater treatment	Clinoptilolite (natural) Chabazite (natural) Mordenite (natural) Phillipsite (natural)	Uptake of NH_4^+ and heavy metals from waste streams
Nuclear waste treatment	Clinoptilolite (natural) Chabazite (natural) Phillipsite (natural) Mordenite (natural) Mordenite (synthetic) Ionsiv IE-96 (synthetic) Ionsiv A-51 (synthetic)	Uptake of $^{137}\text{Cs}^+$, $^{90}\text{Sr}^{2+}$ and other radionuclides
Animal food supplement	Various (natural)	Regulation of NH_4^+ and NH_3 levels in stomach
Animal food supplement	Various (natural)	Scavenging of radionuclides following contamination of livestock
Fertilizer	Various NH_4^+ forms (natural), often those used to remove NH_4^+ from wastewater	Slow release of NH_4^+ (and other cations)

The empirical structural formula for an aluminosilicate zeolite may be given as

where the framework is constructed from the entities within the square brackets and the water molecules and charge-balancing cations (M)

occupy the interstitial space. The $x/n M^{n+}$ cations are present to counterbalance the x units of negative charge on the framework due to the presence of $x \text{ AlO}_2$ groups. In many cases, ion exchange reactions in zeolites may reach completion, that is, all of the charge-balancing cations (M) initially present are capable of being replaced by the ingoing cation.

Figure 2 A representation of some of the possible positions of exchangeable cations in the structures of zeolites A (A) and X (B). Note: the two structures are not shown on the same scale. Reproduced with permission from Stucky GD and Dwyer FG (eds) (1983) *Intrazeolite Chemistry*. ACS Symposium Series, vol. 218, p. 288. Washington, DC: American Chemical Society.

Incomplete ion exchange reactions In some cases, some of the cations are constrained within the structure and are nonexchangeable. Such cations are introduced into small cavities in the structure during growth of the zeolite crystal. This situation is common with feldspars and feldspathoids, which are similar in composition to zeolites, but possess more limited porosity. Even in instances when all charge-balancing cations in the zeolite are physically exchangeable, the total theoretical exchange capacity might not be obtained practically.

There are several reasons for incomplete ion exchange; the three most important of these are given below and illustrated schematically in Figure 3.

1. The most obvious cause of partial or nonexistent exchange is ion-sieving, where the cation to be exchanged into the zeolite is too large, or has a hydration sphere which is too large and robust for it to have unrestricted access to the pores of the zeolite. Univalent cations will typically reach 100% exchange, except in limiting cases such as large cations combined with small-pore zeolites. Ion-sieving is more commonly observed with multiply charged cations, which tend to have larger hydration spheres on account of their higher charge densities. Zeolites which possess more than one ion exchange site (see Figure 2) may display ion-sieving properties depending on the thermodynamics of the exchange reactions occurring at the various sites. The sites which offer the greatest thermodynamic advantage are exchanged first, while the less favourable sites may not exchange at all.
2. Volumetric exclusion may occur if bulky (organic) cations are exchanged into zeolites of high charge density. Here, the volume occupied by the cations may reach that available in the pores of the crystal before complete exchange has occurred.
3. A third reason for limited exchange to be observed is when multivalent cations are exchanged into zeolites of low charge density. As the density of ion exchange sites decreases, the mean separation between adjacent sites increases, until a point is reached where multivalent cations are unable to satisfy two or more cation exchange sites because of the distance between them. Table 2 illustrates this point by listing the maximum exchange limits observed for several multivalent cations in samples of zeolites ZSM-5 and EU-1 possessing a range of Si/Al ratios.

It is easy to visualize the limiting factors of ion exchange under equilibrium conditions; however, practical ion exchange may have also kinetic limitations. A particular example of when the desired ion

Figure 3 The principal reasons for limitations to ion exchange reactions found in zeolites. (A) Ion-sieving; (B) volume exclusion; (C) low charge density (with multivalent cations). The lightly shaded regions represent an extract of the zeolite framework. For clarity, only *ingoing* cations are shown.

exchange is kinetically limited but still capable of reaching 100% of the theoretical capacity is the softening of water.

Zeolites are used in vast quantities in the detergent industry as a water-softening additive for laundry detergents – up to 30% by weight of most modern washing powders is zeolite. The zeolite is added principally to remove calcium and magnesium and thus prevent their precipitation with surfactant molecules. Zeolite A is most commonly used, due to its high ion exchange capacity, which is a consequence of the framework possessing the maximum possible number of aluminium atoms (Si : Al = 1 : 1). Recently, zeolite

^a Number of aluminium atoms in framework per unit cell.

MAP (Maximum Aluminium P), also with Si : Al = 1 : 1, has been introduced into some detergents. Although the Mg²⁺ ion (radius 0.07 nm) is considerably smaller than the Ca²⁺ ion (radius 0.1 nm), its exchange into the zeolite is far less facile than that of Ca²⁺, due to its large, tight hydration sphere (the radii of the hydrated Ca²⁺ and Mg²⁺ cations are estimated to be 0.42 and 0.44 nm, respectively). **Figure 4** shows the kinetics of exchange of Ca²⁺ and Mg²⁺ into Na-A zeolite. The major restriction to the hydrated Mg²⁺ cation is the 0.42 nm window in zeolite A through which it must pass to gain access to the exchange sites within the structure. In order for the ion exchanger to be effective as a water softener for detergents, it must reduce water hardness within a few minutes of beginning the wash cycle. While zeolites A and MAP perform well at removing calcium from hard water quickly, their performance towards magnesium is generally poor. Despite the kinetic limitations, Ca²⁺ and Mg²⁺ are fully exchangeable into zeolite A, although selectivity is greater for Ca²⁺ (**Figure 5**). Detergent-grade zeolites possess small crystallite sizes in

order to provide acceptable kinetics of Ca²⁺ exchange.

Materials closely related to zeolites

Semicrystalline zeolites Some interest has been shown in the ion exchange properties of zeolite precursors, which are obtained by quenching a zeolite synthesis mixture before it has fully crystallized. In these semicrystalline materials, some larger windows and pores are present than in the crystalline counterpart because the structure has not fully formed. This leads to ion exchange selectivities which are different from the crystalline material. Also, their ion exchange capacities are lower than the corresponding crystalline zeolites. The materials typically show weak zeolite X-ray diffraction patterns, and are

**Figure 4** Kinetics of exchange of Ca²⁺ and Mg²⁺ for 2Na⁺ in zeolite A. Circles, Ca²⁺ exchange; triangles, Mg²⁺ exchange. Data were determined at 25°C, pH 10 and at a solution concentration of 0.05 mol equiv. L⁻¹.**Figure 5** Isotherms for Ca²⁺/2Na⁺ and Mg²⁺/2Na⁺ exchange in zeolite A. Circles, Ca²⁺ exchange; triangles, Mg²⁺ exchange. Data were determined at 25°C, pH 10 and at a solution concentration of 0.05 mol equiv. L⁻¹.

Figure 6 Kinetics of exchange of Ca^{2+} and Mg^{2+} for 2Na^+ in the semicrystalline precursor to zeolite A. Circles, Ca^{2+} exchange; triangles, Mg^{2+} exchange. Data were determined at 25°C , pH 10 and at a solution concentration of $0.05 \text{ mol equiv. L}^{-1}$.

thus not totally amorphous, but possess some short-to-medium range order. Semicrystalline precursors to zeolites have been investigated as potential water softeners with enhanced magnesium performance for detergent use. The materials show slightly limited capacities for both calcium and magnesium, but the selectivity ratio of $\text{Mg} : \text{Ca}$ is higher than that in the fully crystalline counterpart. In the kinetics of exchange, one sees the influence of the population of larger windows and pores. The rate of Mg^{2+} exchange approaches that of Ca^{2+} exchange, since the openness of the semicrystalline structure presents less limitation to the diffusion of large hydrated cations (see **Figure 6** and compare with **Figure 4**). Despite the improvement in Mg^{2+} exchange properties relative to Ca^{2+} , the performance of such zeolite precursors is probably too poor for detergent applications.

Materials with nonaluminosilicate frameworks
Zeolite-like structures composed partially or wholly of oxides other than those of Al and Si such as silicoaluminophosphates (SAPOs), metal aluminophosphates (MeAPOs), stannosilicates, zincosilicates, titanosilicates and beryllphosphates are expected to possess ion exchange properties, although few data exist in the literature. Of these materials, the titanosilicates have received the most attention. Recently, the titanosilicate TAM-5 has been developed; this exhibits high selectivity for Cs^+ in the presence of high concentrations of other alkali cations and over a pH range from below 1 to above 14. Also, high selectivity of this material for Sr^{2+} in basic media has been observed. These high selectivities, and its stability to solutions covering this pH range, has led to commercialization of

the material by UOP as Ionsiv IE-910 (powder) and Ionsiv IE-911 (granules) for use in nuclear waste treatment.

Particularly interesting ion exchange properties are shown by materials possessing high electric field strengths, which may arise with frameworks composed of oxides of elements with valencies differing from each other by more than one unit. An example is the beryllphosphate $\text{Na}_8[(\text{BeO}_2)_8(\text{PO}_2)_8] \cdot 5\text{H}_2\text{O}$, which has the same structure as the aluminosilicate zeolite gismondine (or synthetic zeolite P). Beryllium and phosphorus are strictly alternating in the structure and have valencies of $+2$ and $+5$ respectively, giving rise to a framework with alternating -2 and $+1$ nominal charges (on Be and P), as opposed to -1 and 0 for Al and Si in the aluminosilicate analogue. Due to the high electric field gradient, hard cations tend to be favoured over soft ones. Thus, magnesium is favoured kinetically over calcium; the diffusion coefficient for exchange of Mg^{2+} into $\text{Na}_8[(\text{BeO}_2)_8(\text{PO}_2)_8] \cdot 5\text{H}_2\text{O}$ is more than three times higher than that of Ca^{2+} under the same conditions (**Figure 7**), which is a reversal of the situation seen in the aluminosilicate zeolites (compare **Figures 7** and **4**). The relatively slow kinetics of exchange may be attributed to the small window size of the beryllphosphate material (the beryllphosphate unit cell is smaller than the aluminosilicate one). Univalent cations also exhibit unusual exchange characteristics with $\text{Na}_8[(\text{BeO}_2)_8(\text{PO}_2)_8] \cdot 5\text{H}_2\text{O}$, due in part to the relatively short Be–O and P–O bonds and the rigidity of the structure. High resistance is experienced by ingoing cations and large hysteresis loops are seen in, for instance, the exchange of K^+ for Na^+ , while the same reactions in the aluminosilicate analogue do not exhibit hysteresis (compare

Figure 7 Kinetics of exchange of Ca^{2+} and Mg^{2+} for 2Na^{+} in $\text{Na}_8[(\text{BeO}_2)_8(\text{PO}_2)_8] \cdot 5\text{H}_2\text{O}$. Circles, Ca^{2+} exchange; triangles, Mg^{2+} exchange. Data were determined at 25°C , pH 10 and at a solution concentration of $0.05 \text{ mol equiv. L}^{-1}$. Interdiffusion coefficients (D): $D_{(\text{Ca})} = 2.0 \times 10^{-18} \text{ m}^2 \text{ s}^{-1}$; $D_{(\text{Mg})} = 6.5 \times 10^{-18} \text{ m}^2 \text{ s}^{-1}$. Figures 8 and 9). Hysteresis occurs when the two end-members of exchange (in this case, the pure K and Na forms) are mutually immiscible, and form separate phases which can usually be differentiated by X-ray diffraction. The two phases will be present simultaneously over a range of cation compositions (in intermediate Na/K forms), depending on the degree of immiscibility of the two end-members.

Solid-state ion exchange in zeolites The exchange of cations from one solid to another, probably mediated by the presence of small quantities of water, is referred to as solid-state ion exchange. This is a technique which is useful for the preparation of catalysts, that is, the introduction of cations which are only sparingly soluble, or which process hydration spheres which are too large to allow easy diffusion into the

cavities of the zeolite from solution. The technique may involve thermal treatment (at temperatures up to 500°C) of an intimate mixture of the zeolite and the salt containing the cation to be exchanged (or another zeolite) although, in some instances, exchange has been observed to occur under ambient conditions. Another advantage of the solid-state approach to preparing catalysts is the avoidance of generating large quantities of waste exchange solution.

Clays and Other Layered Materials

Clays are one of the most abundant materials present on the earth's surface. They constitute a large component of soil, while many ceramic and building materials as well as industrial adsorbents and catalysts contain clay. Soils owe their ability to sustain plant life largely to clays which have the ability to exchange ions with their surroundings. Clays are typically composed of sheets of linked SiO_4 tetrahedra, which are connected to $\text{Al}(\text{OH})_6$ octahedra. If one sheet of silica interacts with a plane of $\text{Al}(\text{OH})_6$, then a two-tier sheet ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$) typical of kaolinite is obtained. If the octahedral plane is sandwiched between two silica sheets, then a three-tier sheet is obtained ($\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2$), as found in the smectite and mica clays. The sheets are bonded to one another via covalent bonds between the silica and alumina sheets to yield a layer. It is how these layers stack together (via electrostatic and van der Waals forces only) which give clays many of their interesting properties, and gives a large degree of flexibility to the structures. Clay-like materials may be composed of oxides of elements other than silicon and aluminium.

The three principal types of clay – single-layer, nonexpandable double-layer and expandable double-layer – have been introduced by Dyer. Clays may be either cationic (exhibiting cation exchange properties) or anionic (anion exchangers). The former type is more common, accounting for the majority of naturally occurring clays; typical examples are montmorillonite and bentonite. Anionic clays, such as hydrotalcite, occur rarely in nature, but may be synthesized in the laboratory. Layered materials composed of neutral layers also exist, although they possess little or no intrinsic ion exchange capability. Table 3 lists some common types of layered material possessing cationic, anionic and neutral layers.

Pillared clays Expandable cationic clays may be converted into pillared clays by exchanging some or all of their charge-balancing cations with bulky inorganic species such as $[\text{Al}_{13}\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}]^{7+}$ or $[\text{Zr}_4(\text{OH})_{14}(\text{H}_2\text{O})_{10}]^{2+}$ and then calcining the composites to dehydrate and dehydroxylate the pillaring species, leaving hydroxy/oxide pillars. An interesting pillaring process is that involving ion exchange with a cationic 'templating' agent (cetyltrimethylammonium), followed by the synthesis of a mesoporous silica phase around the template cations. The resultant materials, in which the clay layers are propped apart by the mesoporous silica, possess surface areas up to $800 \text{ m}^2 \text{ g}^{-1}$ and interlayer spacings of 3.3–3.9 nm.

For layered materials with anion exchange properties, like layered double hydroxides, species such as $[\text{V}_{10}\text{O}_{28}]^{6-}$ and $[\text{H}_2\text{W}_{12}\text{O}_{40}]^{6-}$ may be exchanged with anions residing between the layers to increase the interlayer spacing.

Table 3 Examples of layered materials

Layer charge	Example
Neutral (no intrinsic ion exchange capability) ^a	TaS ₂ MoO ₃
Positive (anion exchange properties)	Layered double hydroxides: $[\text{M}_I^{I+} \dots \text{M}_K^{K+}(\text{OH})_2]^{x+} + [\text{X}_n^n]^{x-} \cdot z\text{H}_2\text{O}$ Hydroxy double salts: $[\text{M}_I^{I+} \dots \text{M}_K^{K+}(\text{OH})_{3(1-y)}]^{(1+3y)+} + [\text{X}_n^n]^{(1+3y)-} \cdot z\text{H}_2\text{O}$ ($\text{X}^{n-} = \text{Cl}^-, \text{NO}_3^-, \text{SO}_4^{2-}, \text{CO}_3^{2-}, \text{H}_5\text{C}_2\text{O}^-, \text{etc.}$)
Negative (cation exchange properties)	Smectite clays (low charge density) Micas M ^{IV} H-phosphates (high charge density, e.g. α -ZrP, γ -ZrP) Layered titanates Silicic acids

^aNeutral layered materials may undergo a type of ion exchange reaction via redox intercalation, whereby a neutral species is intercalated, followed by a transfer of electrons between the layer and the guest species. Thus both the layer and the intercalated species become charged.

While pillared clays usually offer advantages over normal clays in terms of their higher surface areas, higher sorptive capacities and greater ion exchange capacities, these properties begin to be diminished when the density of pillars becomes too great and the interlayer space becomes filled with pillars. Pillared clays are seldom employed as ion exchangers; their main applications lie in the fields of catalysis and adsorption.

Metal Phosphates

The most important and widespread of the metal phosphates is α -zirconium phosphate ($\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, or α -ZrP), which has an expandable layer structure. Each layer possesses a central plane of octahedral Zr atoms linked to two outer sheets of monohydrogen phosphate groups. The hydrogen form has an interlayer spacing of 0.76 nm, corresponding to a void space with diameter 0.26 nm. Although the calculated surface area of α -ZrP approaches $1000 \text{ m}^2 \text{ g}^{-1}$, in the unexpanded H form the surface area available to N_2 is only $5 \text{ m}^2 \text{ g}^{-1}$.

Another crystalline form of zirconium phosphate γ -ZrP ($\text{Zr}(\text{PO}_4)(\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}$), is formed by a central zirconium phosphate sheet in which the PO_4 groups are linked solely to octahedral Zr atoms; this sheet is linked to dihydrogen phosphate groups to yield the γ -ZrP structure. The complex interlinking results in a more rigid framework in which only *c.* 50% of the theoretical ion exchange capacity is normally obtained.

Swelling of zirconium phosphates The interlayer cavities in α -ZrP of 0.26 nm are accessible to only small and poorly hydrated cations. A certain degree of expansion of the interlayer distance may occur concomitantly with these exchanges. Larger or more strongly hydrated ions do not readily exchange with α -ZrP. However, since the layers are held together principally by electrostatic forces, the distance between them can be increased to allow access of larger ions according to the following mechanism.

The acid form of an α -ZrP possesses H^+ cations which stabilize the negative charge on the $\text{Zr}(\text{PO}_4)_2$ units. A number of these protons may be neutralized by addition of hydroxide ions via the solution phase. This causes negative charge to build up on the layers, causing electrostatic repulsion and forcing the layers apart. Once the material has swelled, access to the exchange sites by larger and more strongly hydrated cations is possible. This view may be slightly oversimplified, since migrating OH^- ions would naturally be accompanied by cations (to preserve electroneutrality in both the solid and solution phases). It is more likely

that the above two-step process actually occurs as a one-step process driven by the neutralization reaction.

'Catalytic' exchanges in α -ZrP The interlayer spacing of α -ZrP may be too small to allow large cations access (a situation anomalous to ion-sieving in zeolites). For instance, the Mg^{2+} ion will not exchange with the protons in α -ZrP directly. However, in the presence of sodium, some magnesium exchange does occur. The process is shown conceptually below.

The hydrated Mg^{2+} ion is too bulky to reach the exchange sites between the layers of the acid form, while the smaller hydrated Na^+ ion is not. The partial exchange of Na^+ for H^+ causes a swelling of the interlayer spacing to a point which allows the hydrated Mg^{2+} to exchange.

Heteropolyoxometalates

Heteropolyoxometalates, or heteropolyacids (HPAs) and their salts are materials which are finding widespread applications as acidic and/or redox catalysts. The most common examples are those with the Keggin structure, composed of a central hetero species, typically PO_4^{3-} or SiO_4^{4-} , surrounded by 12 transition metal oxide octahedra, typically MoO_6 or WO_6 , as depicted in Figure 10. The octahedra and central hetero species are linked via shared oxygens to yield materials with the formula $[\text{XM}_{12}\text{O}_{40}]^{n-}$ where $\text{X} = \text{P}$ ($n = 3$) or Si ($n = 4$) and $\text{M} = \text{Mo}$ or W . Many other structure types are known, with up to 40 transition metal octahedra per molecule. The negative charge is balanced by protons in an HPA and by certain cations in HPA salts. The charge-balancing cations are in many cases partially or wholly exchangeable, and physical properties such as solubility, surface area and porosity may vary widely depending on the nature of the cation (Table 4).

Heteropolyoxometalates are principally used as catalysts. Due to the high solubility of many of the cationic forms of heteropolyoxometalates in aqueous media, their application as ion exchangers has been limited. Apart from ammonium phosphomolybdate and ammonium phosphotungstate which possess low solubility and have been used to scavenge radioactive caesium, and $[\text{NaP}_5\text{W}_{30}\text{O}_{110}]^{14-}$, which has been shown to have high selectivity for lanthanide and certain multivalent ions, comparatively few data are

Figure 10 The structure of $[XM_{12}O_{40}]^{n-}$ where X (P or Si) is located at the centre and is surrounded by 12 metal oxide octahedra. available concerning the ion exchange properties of the HPAs.

Hydrous Oxides

Hydrous oxides are amorphous metal oxides, on the surface of which exist hydroxyl groups which are

present as a necessity to terminate the structure (see Figure 1A). The general formula for a hydrous oxide is $[M^{(n)}O_{(n-x)/2}(OH)_x \cdot wH_2O]_m$, where the central cation, M , is n -valent (n is typically ≥ 3). Most of the metals in the periodic table are able to form hydrous oxides which exhibit ion exchange properties. However, for the material to be applied as an ion exchanger, it must be stable under the conditions used for exchange. In particular, solubility can be a deciding factor in the utility of hydrous oxides; stability to pHs extending from strongly alkaline to strongly acidic may be necessary. Those hydrous oxides comprised of large, low valent cations or small, multivalent cations tend to be soluble, while those intermediate between the two extremes are stable. Typical examples of acid- and alkali-stable hydrous oxides are those of Al^{III} , Ga^{III} , In^{III} , Si^{IV} , Sn^{IV} , Ti^{IV} , Th^{IV} , Zr^{IV} , Nb^V , Bi^V , Mo^{VI} and W^{VI} . Many of the materials are amphoteric, that is, they can act as either cation or anion exchangers depending on, principally, the pH of the electrolyte solution and the basicity of the metal forming the hydrous oxide (the strength of the metal–oxygen bond relative to the oxygen–hydrogen bond).

The change of a commercial alumina from cation exchanger to anion exchanger with varying pH is shown in the chapter by Dyer (Figure 8). The amphoteric nature of hydrous oxides may be illustrated schematically thus:

Table 4 Changes in surface properties of phosphomolybdates and phosphotungstates upon ion exchange

Approximate composition of HPA salt ^a	Surface area by N_2 BET ($m^2 g^{-1}$) ^b	Pore volume $\times 10^3$ ($cm^3 g^{-1}$)	Mean pore radius (nm)
HPMo, NaPMo, (MeNH ₃)PMo	Essentially nonporous		
(NH ₄)PMo	193	52	1.3
KPMo	40	15	0.9
CsPMo	145	6	1.4
HPW, NaPW, AgPW, (MeNH ₃)PW, (Me ₃ N)PW	Essentially nonporous		
(NH ₄)PW	128	50	1.0
KPW	90	31	0.9
CsPW	163	34	1.4
HSiW, NaSiW, KSiW	Essentially nonporous		
(NH ₄)SiW	117	40	1.0
CsSiW	150	52	1.0
RbSiW	116	40	1.0

^a PMo, PW and SiW represent $(PMo_{12}O_{40})^{3-}$, $(PW_{12}O_{40})^{3-}$ and $(SiW_{12}O_{40})^{4-}$ respectively. The charge-balancing cation indicated is assumed to be fully exchanged into the HPA, although some variation of composition is inevitable. Note that the surface properties will vary slightly depending upon the preparation and exact composition of the HPA.

^b Surface area determined using the Brunauer, Emmett and Teller isotherm approach.

Cation exchange typically takes place in alkaline solution, while anion exchange is preferred in acidic solution. Dissociation of $M-O-H$ near to its isoelectric point allows both exchange mechanisms to operate simultaneously.

Silica, the most common and extensively studied of the hydrous oxides, is a weakly acidic cation exchanger. The physical properties of silica, particularly the porosity and surface area, vary widely depending upon the method of preparation. Generally, multivalent cations interact more strongly with the silica surface than do univalent ones, while in all cases the interactions are relatively weak and ion exchange is facile. Silica possesses between 0.5 and 0.8 hydroxyl groups per nm^2 on its surface.

Miscellaneous Materials

A number of specific materials have been discussed in this chapter. There are, however, numerous inorganic materials possessing ion exchange properties which have not been mentioned. In this section, a few of those materials which exhibit interesting ion exchange properties are introduced briefly. The list is far from complete, but serves to illustrate the diversity of ion exchange materials.

- Hydroxyapatites may undergo limited ion exchange reactions. While the calcium form ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) is the most common (it is a major component of teeth and bones), pure exchange end-members of Sr^{2+} , Cd^{2+} and Pb^{2+} are known, while various cations may form intermediate mixed-cation phases. The Sr^{2+} end-member, due to a slight lattice expansion, possesses superior ion exchange properties compared to Ca-hydroxyapatite. Of the Sr-hydroxyapatites, that with a (non-stoichiometric) Sr/P ratio of 1.73 has the highest ion exchange capacity of those measured. It is interesting that the presence of HCl may assist the ion exchange reaction by formation of a chlorapatite phase. This may be an example of simultaneous anion and cation exchange.
- Copper hexacyanoferrates, $\text{Cu}_2^{\text{II}}\text{Fe}^{\text{II}}(\text{CN})_6 \cdot x\text{H}_2\text{O}$ and related compounds show quite promising exchange properties for Cs^+ , and have been investigated as agents for nuclear waste treatment. On passing caesium-containing waste through a column of $\text{Cu}_2^{\text{II}}\text{Fe}^{\text{II}}(\text{CN})_6 \cdot x\text{H}_2\text{O}$ at room temperature, decontamination factors (ratios of pre-column to post-column Cs^+ concentrations) of 10^3 can be achieved.
- Lithium manganate containing mixed-valence manganese ions exhibits unusual ion exchange properties, in that it undergoes combined ion exchange and redox reactions. Upon acid treatment of $\text{LiMn}^{\text{III}}\text{Mn}^{\text{IV}}\text{O}_4$, the Mn^{III} is oxidized to Mn^{IV}

and Li is displaced from the structure thus:

The resulting spinel structure ($\gamma\text{-MnO}_2$) is highly selective for Li, and will readily re-insert Li^+ to regain the Li-manganate spinel:

This type of exchange reaction is often referred to as the ion memory effect.

- Iodide ions may be efficiently exchanged for nitrate ion using $\text{BiPbO}_2\text{NO}_3$ in solutions of $\text{pH} \geq 13$. Under such conditions, the theoretical exchange capacity of 2 mmol g^{-1} is approached.

Conclusions

As with any commercial venture, improvements to large scale ion exchange processes will always be sought. With the advances made in structural characterization and synthetic methods, it is becoming increasingly possible to tailor the ion exchange properties of materials to specific needs. Thus, the strive for water-softening zeolites for detergents with greater capacity, selectivity and rate of exchange for Ca^{2+} and Mg^{2+} , or for exchangers with better stability over wide pH ranges coupled with high selectivity for certain ions present in waste streams will be ever-present. Recent advances have made some significant steps in these particular directions:

- The field of nuclear waste clean-up has spawned a number of interesting materials; inorganic exchangers are now available which have good structural stability in waste streams and exhibit high selectivities for Cs^+ and Sr^{2+} in the presence of large excesses of other ions over wide pH ranges.
- Zeolites continue to be used in vast quantities as water softeners in detergents. A significant recent development has been the introduction of a new detergent zeolite MAP, which offers improved performance over zeolite A.

Interesting ion exchange properties are exhibited by framework materials possessing high electric field gradients, such as the beryllophosphates. However, this particular area is deserving of more extensive exploration.

The prediction of ion exchange behaviour for a particular material is possible given data for exchange reactions in that material under

different conditions. However, the prediction of ion exchange properties on the basis of the structure of the exchanger alone may become more readily possible through the use of computer modelling.

The study of ion exchange behaviour under the influence of microwave radiation is an area which preliminary research has suggested may be interesting.

It has long been known that many polyvalent cations can be precipitated as amorphous phosphates from dilute solutions and these salts are useful in gravimetric analysis. More recently it has been recognized that many of these precipitates contain exchangeable acid protons and behave as inorganic ion exchangers. Phosphates of tetravalent metals such as Zr(IV), Ti(IV) and Sn(IV) have been found to possess high ion-exchange capacity and good stability in acid and oxidizing solutions and when exposed to high temperatures and ionizing radiation. Because of these properties, their potential uses for the purification of nuclear reactor cooling water or for the treatment of radioactive waste were investigated during the late

1950s and early 1960s, especially in nuclear centres. The ion-exchange properties of amorphous zirconium, titanium and tin phosphates were reviewed by Amphlett in 1964. However, the beginning of the chemistry of layered phosphates may be dated back to 1964, when Clearfield and Stynes refluxed zirconium phosphate gel in phosphoric acid solutions in an attempt to produce a material which was more resistant to hydrolytic attack than the original gel. The microcrystals obtained were found to possess a layered structure, called the α -type, and with the composition $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$. This compound was indeed more resistant to hydrolytic attack than the amorphous analogue. It possesses two exchangeable protons per formula weight and is an excellent intercalating agent of protophilic species and a pure solid-state protonic conductor. Moreover, it is possible to correlate the observed properties with the structural

features. These findings stimulated research on the synthesis of layered phosphates of other polyvalent metals. The progress made up to 1982 was reviewed by Clearfield, and by Alberti and Costantino, and from that date the field of layered phosphates has been continuously expanding with the discovery and resolution of the structure of new crystalline phases. It was found that zirconium (or titanium) phosphate has an isomorphous modification, named γ -type, and the composition $\text{Zr}(\text{PO}_4)(\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}$. This compound, as well as having cation exchange and intercalation properties, undergoes a topotactic anion exchange reaction of the dihydrogenphosphate groups with other anions. Most recently, the preparation of a new crystalline layered phase, named λ -type, and having the composition $\text{Zr}(\text{PO}_4)\text{Cl}(\text{CH}_3)_2\text{SO}$, has opened new research possibilities. This article deals with the preparation, structure, ion exchange and intercalation properties of layered phosphates and phosphonates of polyvalent metals, mainly zirconium, and with their application. Exfoliation of layered phosphates which allows the preparation of mixed layered phosphates or thin-layer coatings on substrates such as silica and alumina or of microporous pillared layered phosphates will be described.

However, before discussing in more detail the above-mentioned materials, it is worth commenting briefly on the preparation, ion exchange properties and application of amorphous zirconium phosphate, because of its commercial availability and renewal of interest in its use in nuclear waste treatment.

Amorphous zirconium phosphate is easily prepared by adding a solution of zirconium salts to a solution of phosphoric acid in acid media ($2\text{--}4 \text{ mol dm}^{-3} \text{ HCl}$). The precipitate can be appropriately treated to obtain the exchanger in glassy, granular or powdered form. The composition is best described by the formula $\text{Zr}(\text{HPO}_4)_{2-x}(\text{OH})_{2x} \cdot n\text{H}_2\text{O}$, x ranging between 0 and 0.2. The material is stable up to 180°C (temperature at which condensation of phosphates to pyrophosphates starts) in acidic medium (e.g. $6 \text{ mol dm}^{-3} \text{ HNO}_3$), and has a remarkable resistance to strong doses of ionizing radiation. The ion exchange capacity ranges from 4 to 6 mequiv. g^{-1} . At low loading, the exchanger prefers cations with lower hydrated ionic radius and higher charge. Its use for the selective removal of ^{137}Cs and ^{89}Sr radioisotopes from aqueous nuclear wastes in ultrafiltration and fluidized bed systems has been proposed. Amorphous zirconium phosphate, because of its bio-compatibility and high insolubility, is used to fill cartridges for the removal of urea from blood in haemodialysis machines.

Layered Phosphates of Groups 4 and 14, 5 and 15 elements

Preparation

Numerous layered phosphates of the elements of the groups 4, 5, 14 and 15 of the periodic table have been synthesized and many of them are listed in Table 1, together with their interlayer distance, the free area

Table 1 Formulae and some properties of layered phosphates of groups 4, 14 and 5, 15 elements

Formula	Density (g cm^{-3})	Ion exchange capacity ($\text{mmol H}^+ \text{g}^{-1}$)	Interlayer distance (\AA)	Free area (\AA^2)*
$\alpha\text{-Ti}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	2.61	7.76	7.56	21.6
$\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$	2.72	6.64	7.56	24.0

*Area associated to each $-\text{OH}$ group on the plane.

surrounding the surface phosphate groups, density and calculated ion exchange capacity. It may be seen that, except for carbon, α -type phosphates of all the elements of groups 4 and 14 have been obtained. They are prepared with procedures similar to those used to obtain $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, that is, by refluxing the amorphous precipitates in phosphoric acid ($10\text{--}12 \text{ mol dm}^{-3}$). An alternative procedure, especially used for Zr and Ti hydrogenphosphates, involves direct precipitation from solutions containing phosphoric acid and Zr (or Ti) fluoro-complexes. The degree of crystallinity of the precipitates may be controlled by modifying the velocity of removal of the complexing agent, as gaseous HF. With this method, crystals of millimetre dimensions have been obtained. Note that only Zr(IV) and Ti(IV) can form phosphate dihydrogenphosphates of γ -type. The preparation involves the slow decomposition of fluoro-complexes in an $\text{NH}_4\text{H}_2\text{PO}_4$ solution. The precipitate, e.g. $[\text{Zr}(\text{PO}_4)(\text{NH}_4\text{HPO}_4)]$, is then converted into its hydrogen form by treatment with HCl solution.

Tetravalent elements with large dimensions, such as Ce(IV) and Th(IV) do not give rise to layered phosphates of α - or γ -type. The acid phosphates of these elements have been obtained in fibrous form suitable for the preparation of fully inorganic, self-consistent papers, thin films or membranes. The acid phosphates of groups 5 and 15 elements have been obtained by dissolving the oxides in concentrated phosphoric acid and heating to 270°C . $\text{HSb}(\text{PO}_4)_2$ can be obtained by treating the potassium salt with a strong acid solution. Group 5 elements also produce non-acid layered phosphates of formula XOPO_4 ($\text{X} = \text{V}, \text{Nb}, \text{Ta}$) and structure similar to that of $\text{Zr}(\text{PO}_4)\text{Cl}(\text{CH}_3)_2\text{SO}$. Vanadyl phosphate is one of the rare examples of a layered phosphate which has a low electronic conductivity and is capable of redox intercalation reactions similar to those shown by graphite or layered dichalcogenides. Generally speaking, layered phosphates possess good chemical and thermal stability. Layered $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ is a very insoluble compound, stable even in highly concentrated non-complexing acid solutions. The interlayer water is lost after prolonged heating at 110°C while the condensation water of monohydrogenphosphates to pyrophosphates is lost at $450\text{--}500^\circ\text{C}$. Molybdenum and some divalent cations such as Fe, Cd and Mn also form layered phosphates but their physical and chemical properties have not been investigated thoroughly.

Structural Aspects

Layered solids are molecular crystals formed by the packing of giant planar macromolecules called layers or lamellae. The bonds between the atoms present in

the layer are strong, primarily covalent, while those between the atoms of adjacent lamellae are weak, essentially of the van der Waals type. Thus, layered solids generally exhibit a high anisotropy in their physical properties. The reactivity of layered solids is shown by the intercalation reaction, that is, the reversible insertion of guest species into the interlayer region without appreciable modification of the structure of the lamellae which move apart to accommodate the guest species. Hence, the structural aspects of a layered solid are closely connected with the bidimensional structure of the layers. The Greek letter prefix that often indicates a layered phosphate is related to the layer structure. The structures of the layered phosphates listed in Table 1 will be illustrated with reference to the α -, γ - and λ -zirconium phosphates, but the phosphates of other elements have similar structures. Geometrical considerations indicate that bidimensional structures can be easily formed by concatenation through the vertices of MO_6 octahedra (M being the polyvalent metal) of suitable dimension, and of PO_4 tetrahedra. In the present case different concatenation gives rise to different layer structures.

Crystals of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ are monoclinic with $a = 9.060(2) \text{ \AA}$, $b = 5.297(1) \text{ \AA}$, $c = 15.14(3) \text{ \AA}$, and $\beta = 101.71(2)^\circ$, space group $\text{P}2_1/\text{n}$. The sequence of two layers is shown in Figure 1. Each layer may be described as the concatenation of ZrO_6 octahedra and O_3POH tetrahedra. Note that each tetrahedron bridges three different octahedra and these, in turn, bridge six tetrahedra. The layer is a planar macromolecule bearing acid P-OH groups on the

Figure 1 Computer-generated representation of the sequence of two layers of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$. (Crystal data from Clearfield A and Smith GD (1969) *Inorganic Chemistry* 8: 431–436.)

Figure 2 Computer-generated representation of the sequence of two layers of $\text{HSb}(\text{PO}_4)_2$. (Crystal data from Piffard Y, Oyetola S, Courant S and Lachgar S (1985) *Journal of Solid State Chemistry* 60: 209–213.)

surfaces. The distance between adjacent phosphate groups on one side of the layer is 5.3 \AA and the 'free area' around each P-OH group is 24 \AA^2 . The interlayer distance is 7.56 \AA and the arrangement of the pendant phosphate groups creates six-sided cavities, each containing one water molecule, in the interlayer region. This layered structure is common to the other α -layered phosphates and it is very similar to that of $\text{HSb}(\text{PO}_4)_2$, shown in Figure 2.

The second layer structure, in which two different tetrahedral species are used at the same time, is present in the γ -compound with formula $\text{Zr}(\text{IV})(\text{PO}_4)(\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}$. The γ -layer consists of two ideal planes containing zirconium atoms bonded by tetrahedral PO_4 and H_2PO_4 groups (see Figure 3). The PO_4 group shares all four oxygens with zirconium atoms while the H_2PO_4 shares two oxygens with two different Zr atoms and points the remaining two OH groups towards the interlayer region. The interlayer distance is 12.2 \AA , and the free area surrounding the $\text{P}(\text{OH})_2$ groups on the surface of the layers is 35 \AA^2 .

A third layer structure of great interest can be formed by bridging four different zirconium atoms with a tetrahedral PO_4 group in a slightly different manner from γ -zirconium phosphate, and then by balancing the residual positive charge and completing the octahedral configuration of each zirconium atom with a monovalent anionic ligand, Cl^- and a neutral monodentate ligand, $(\text{CH}_3)_2\text{SO}$, as

Figure 3 Computer-generated representation of the sequence of two layers of $\gamma\text{-Zr}(\text{PO}_4)(\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}$. (Crystal data from Christensen A, Andersen EK, Andersen IKG, Alberti G, Nielsen N and Lehman MS (1990) *Acta Chemica Scandinavica* 44: 865–872.)

illustrated in Figure 4. Note that this structure is essentially the same as that of layered vanadyl phosphate (see Figure 5) and of uranyl phosphate.

Chemical Reactivity

Ion Exchange Properties

The protons of layered acid phosphates are able to diffuse in the interlayer region and these compounds behave as inorganic cation exchangers and proton conductors. Mainly the ion-exchange properties of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ will be considered as these have been investigated extensively. However, the findings apply to the other members of the class. All these compounds are solid acids and the simplest way to completely replace the protons with other cations is by titrating the microcrystals with solutions of the hydroxide of the cation to be exchanged. The

Figure 4 Computer-generated sequence of two layers of $\text{Zr}(\text{PO}_4)\text{Cl}(\text{CH}_3)\text{SO}$. (Data from Alberti G, Bartocci M, Santarelli M and Vivani R (1997) *Inorganic Chemistry* 36: 3574–3575.)

titration curves of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ with alkaline metal hydroxides, in the presence of the corresponding metal chloride, are shown in Figure 6.

It may be seen that the exchange process occurs stepwise. In each plateau of the titration curve the composition of the solution, and hence also the pH, is constant. Since temperature and pressure are also

Figure 5 Computer-generated structure of the sequence of two layers of VOPO_4 . (Crystal data from Tietze HR (1981) *Australian Journal of Chemistry* 34: 2035–2038.)

Figure 6 Potentiometric titration curves of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ with the hydroxides of the indicated alkali metal ions, in the presence of the corresponding metal chlorides. constant, the phase rule requires the presence of two solid phases. The X-ray diffraction patterns of samples with increasing metal ion loading indeed indicate the presence of two solid phases, one transforming into the other as the exchange reaction proceeds. According to a model developed by Alberti, ion exchange in the α -phases takes place by diffusion of the cations from the external part of the layered crystals towards the bulk with an advancing phase boundary with the co-existence in the same crystallite of two phases. To illustrate the model consider H^+/Na^+ exchange (see Figure 6 and the scheme in Figure 7). Initially we observe the formation of a phase of composition $\text{ZrHNa}(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$ and interlayer distance 11.8 Å, according to the reaction (the number in parentheses refers to the interlayer distance):

The composition of the exchanged phase does not change until half the protons of the original hydrogen

Figure 7 Schematic representation of the phases formed during the H^+/Na^+ ion-exchange process in $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ micro-crystals.

form have been replaced by Na^+ ions. At the end of the process only the monosodium form is present and the pH of the solution rises to a value at which the following reaction takes place:

Examination of the ion-exchange process

where M is an alkaline metal, shows the following selectivity sequence: $\text{K}^+ > \text{Na}^+ > \text{Li}^+ \gg \text{Rb}^+ \cong \text{Cs}^+$, since potassium uptake occurs at $\text{pH} \cong 2$ while H^+/Cs^+ exchange occurs at $\text{pH} \cong 7$. The different selectivity towards K^+ and Cs^+ is a direct consequence of the structural features of the host. The zeolitic cavities present in the interlayer region of $\alpha\text{-Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, are interconnected by windows of 2.64 \AA width. Therefore, cations such as Rb^+ and Cs^+ that have an ionic diameter greater than 2.64 \AA , as well as highly hydrated divalent and trivalent cations, are not taken up unless energy is supplied to spread the layers apart. Accordingly, a facile exchange of large monovalent ions or of highly hydrated divalent or trivalent cations takes place if precursors with a high interlayer distance such as polyhydrate zirconium phosphate, $\text{Zr}(\text{HPO}_4)_2 \cdot 4\text{H}_2\text{O}$ ($d = 10.4 \text{ \AA}$) or the monosodium form $\text{ZrHNa}(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$ ($d = 11.8 \text{ \AA}$) or some intercalation compounds with alkanols or amines (see below) are employed. A study of the ion exchange isotherms of $\text{ZrHNa}(\text{PO}_4)_2 \cdot 5\text{H}_2\text{O}$ with different monovalent and divalent cations (see Figure 8) revealed the following selectivity order $\text{Ba}^{2+} > \text{Ca}^{2+} > \text{Cs}^+ > \text{K}^+ > \text{Mg}^{2+} > \text{Na}^+ > \text{Li}^+$.

By using suitable precursors, a large number of cations of the periodic table, as well as organic cations or cationic complexes, have been intercalated via ion exchange processes into zirconium phosphate and other layered phosphates. Table 2 states the composition and interlayer distance of a selected number of phases, some of them prepared for practical applications. These layered phosphates possess good thermal resistance and are stable even when exposed to high doses of ionizing radiation.

Zirconium phosphate has been used to perform ion exchange processes in molten salts at high temperatures. Figure 9 shows the Na^+/K^+ forward and reverse isotherms obtained in molten $\text{NaNO}_3\text{--KNO}_3$ mixtures at 450°C .

Good resistance to radiation makes these phosphates particularly suitable for the uptake of dangerous radionuclides such as $^{137}\text{Cs}^+$, $^{89}\text{Sr}^{2+}$ and $^{60}\text{Co}^{2+}$.

bpy = bipyridyl; phen = phenantroline; dmp = dimethylphenantroline.

In addition, zirconium phosphates exchanged with transition metal ions are heterogeneous catalysts and supports for chromatographic separation. For the latter application it should be noted that layered acid phosphates are usually obtained as small platelets ($\sim 1 \mu\text{m}$) and very compact chromatographic columns are usually obtained. The flows are therefore slow while some particles tend to be released into the external solution. This problem may be overcome by

using larger particles, even though the rate of exchange decreases, or by supporting the layers on a suitable support such as silica gel.

Topotactic anion exchange reactions We have seen above that the majority of layered phosphates are inorganic cation exchangers. Layered phosphates of the γ -type show a typical reaction, which formally represents an anion exchange process. A topotactic exchange reaction is defined as the replacement of one group by another without alteration of the host matrix. If we consider the structure of the γ -phases we observe that the dihydrogenphosphate groups, present on the surface of the lamellae, have a net charge of -1 , delocalized over two oxygen atoms. The H_2PO_4^- is weakly bonded to the central tetravalent atom (Zr or Ti) and it may be easily replaced by other suitable groups, when the layered phosphate is equilibrated with a solution containing such groups. Topotactic exchange reactions with phosphites, hypophosphites, phosphonates or phosphinates, according to the general reaction:

are particularly efficient. R is an aliphatic or aromatic organic moiety that may bear a functional group. This simple procedure has allowed the preparation of a large number of new layered phosphate-phosphonates of γ -type with very interesting properties.

Figure 9 Forward and reverse Na^+/K^+ ion-exchange isotherms on layered α -zirconium phosphate in molten NaNO_3 - KNO_3 mixtures at 450°C . (Reproduced with permission from Alberti G and Costantino U (1974) *Journal of Chromatography* 102: 5–29. Copyright: Elsevier Publishing Science, Amsterdam.)

Intercalation Properties

Over time, research on layered phosphates has moved from the study of their ion exchange properties to that of their intercalation properties in great part determined by the presence of Brønsted acid groups in the interlayer region. Both α - and γ -zirconium phosphates are excellent intercalating agents of Lewis bases. The intercalation chemistry of the former has been more widely investigated and we will be mainly concerned with α -zirconium phosphate. Many molecules belonging to various classes of organic compounds (alkanols, glycols, alkyl and aryl amines, heterocyclic bases, aminoacids and dyes) have been intercalated. The corresponding intercalation compounds have been characterized for composition and arrangement of the guest molecules in the interlayer region. Table 3 gives the interlayer distance and composition of some typical examples of intercalation compounds.

Let us examine in more detail the intercalation of *n*-alkylamines that leads to the formation of compounds containing two moles of guest per mole of host, according to the reaction

where R is the *n*-alkyl-chain. The reaction proceeds stepwise with the formation of different phases. At low amine loading we observe the formation of a phase with interlayer distance 10.4 Å and the alkyl-chain axis is almost parallel to the layer plane (see Figure 10A). At half intercalation, the alkyl chains are arranged as a monolayer of extended molecules with the chain axes inclined by 55° with respect to the layer plane (see Figure 10B). At full intercalation *n*-alkylamines give rise to compounds in which the inorganic layer regularly alternates with a bilayer of alkylamines with the *n*-alkyl chain in *trans-trans* conformation (see Figure 10C). The terminal -NH₂ groups are protonated by the hydrogenphosphate groups.

Intercalation compounds with α,ω -alkyldiamines contain one mole of guest per formula weight. The guest molecules are arranged as a monolayer of extended chains and the terminal -NH₂ groups interact with the P-OH groups belonging to two-faced layers. Alkanols and glycols produce intercalation compounds whose composition and arrangement of guest species are similar to those found in alkyl monoamines and diamines, respectively. However, direct intercalation is prevented by the lower basicity of the alkanol OH group, compared to that of the NH₂ group. It is necessary to use as precursors pre-swelled zirconium phosphates.

Table 3 Interlayer distances and guest contents of intercalation compounds of α -zirconium phosphate

Guest molecule	mol Guest/ mol α -ZrP	Interlayer distance (Å)

Heterocyclic bases give rise to non-stoichiometric intercalation compounds and the heterocyclic ring is positioned parallel to the layer plane. For the arrangement of other intercalated guests the reader is referred to recent reviews given in the Further Reading section. Materials with special properties have also been obtained by intercalation. Porphyrins and metalloporphyrins, thionine, methylene blue and rhodamine have been intercalated in α -zirconium phosphate and the materials obtained have been investigated for their optical properties. The possibility of intercalating dyes and of controlling, at least to

Figure 10 Arrangement of *n*-alkyl monoamines intercalated into α -Zr(HPO₄)₂ · H₂O: (A) alkyl-chain axis parallel to the layer plane. (B) Monolayer of extended molecules in *trans-trans* conformation. (C) Bilayer of extended molecules in *trans-trans* conformation.

some extent, molecular orientation is of interest in the preparation of new composite materials for non-linear optic applications. Intercalation of weak Brønsted bases was found to enhance the proton

conduction of the host and some of the compounds obtained have been used as active components in solid-state electrochemical gas sensors. Molecular and chiral recognition properties have been induced

in layered zirconium phosphate by the intercalation of suitable receptors such as aminated β -cyclodextrins, crown ethers or a Pirkle receptor.

Much attention is presently being paid to the possibility of performing reactions in the interlayer region. Polymerization, induced by chemical, thermal or photochemical treatment, of pyrrole, aniline, propargylamine or ε -aminocaproic acid intercalated in layered phosphates, produces interesting composite materials in which the inorganic layers regularly alternate with the polymers formed in the interlayer region.

Exfoliation Process

We have seen that layered polyvalent metal phosphates are obtained as molecular crystals built up by the packing of the layers which are planar macromolecules. These bidimensional macromolecules are usually very thin (5–15 Å), whereas planar dimensions are of the order of μm^2 , depending on the conditions of synthesis. If a layered crystal is exfoliated in single layers, materials with a very large surface area and with enhanced reactivity are obtained. For example, the complete exfoliation of 1 g of α -zirconium phosphate will produce material with a surface area of 950 m^2 . Furthermore, the suspension of the layers may be used to obtain thin films and pellicles or to cover suitable supports.

It is well known that layered smectite clays undergo so-called 'infinite swelling', that is, they disintegrate into single layers or packets of a few layers, when suspended in water. This phenomenon has never been observed in layered phosphates probably because of stronger layer-layer interactions. However, intercalation has made it possible to exfoliate both α - and γ -zirconium phosphates. In the case of α - $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ and of the other α -type layered phosphates a good exfoliation has been obtained by the intercalation of short-chain alkylamines, such as methylamine or propylamine at 100% and 50% loading, respectively. This exfoliation process is shown schematically in Figure 11.

γ - $\text{Zr}(\text{PO}_4) \cdot (\text{H}_2\text{PO}_4) \cdot 2\text{H}_2\text{O}$ is best exfoliated when treated with dimethylamine. Colloidal dispersions containing highly anisotropic particles of nanoscale dimensions have a number of potential applications. After treatment with acids, flocculation allows the formation of completely inorganic pellicles or films useful in assembling the sensor layer of solid-state gas sensors, or to cover glass surfaces for chromatographic application. Composites of layered phosphates and silica gels or pillared layered phosphates have also been prepared from colloidal dispersions.

Solid dispersions of layered phosphates in silica gel Solid dispersions of α - or γ -zirconium phosphates in porous silica can be prepared starting from mixtures of a tetrapropylammonium oligosilicate solution and zirconium phosphates, previously exfoliated with amines. They are formed after gelification of the mixture with acetic acid and subsequent calcination at 650°C to remove the organic moieties. At this temperature zirconium phosphates are transformed into layered pyrophosphates, but non-condensed phosphate groups are still present on the free surfaces of the lamellae. Accordingly, the composites obtained have a large surface area (350–500 $\text{m}^2 \text{g}^{-1}$), good surface ion-exchange capacity and acid catalytic properties. Such composites may find application as stationary phases in chromatography.

Pillared layered phosphates The success obtained in the pillaring of clays to obtain microporous solids with larger pore diameters than those found in zeolites has stimulated research in preparing pillared layered structures based on metal(IV) phosphates. Synthetic strategy requires the insertion of large organic or inorganic cations (pillars) between the layers to prop them apart. If the pillars are sufficiently spaced, a microporous structure is obtained and the dimensions of the channels or diffusion paths are determined by the size of the pillars and their spacing in the interlayer region (see Figure 12).

Inorganic pillars are preferable to organic pillars because of their much higher thermal stability. To obtain thermally stable structures, pillaring has been performed with highly charged polyoxycations such as the Al_{13} Keggin ion $[\text{Al}_{13}\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}]^{7+}$, or $[\text{Zr}(\text{OH})_2(\text{H}_2\text{O})_4]^{8+}$, or inorganic clusters such as $[\text{Nb}_6\text{Cl}_{12}]^{2+}$. After suitable thermal treatment, the layered phosphates contain as pillars, aggregates of inorganic oxides which have considerable thermal stability. The problem of inserting such large pillars has often been overcome by contacting the solution of the pillaring species with colloidal dispersions containing single layers, or packets of a few layers, of tetravalent metal(IV) phosphates. This provides access to the surface POH groups, the exchange reaction and the flocculation of the pillared material. However, the problem of achieving uniform pillar spacing to obtain a narrow distribution of micropores of predictable dimensions has not been completely resolved. The topic is of great interest since materials for molecular sieving and for shape-selective catalysis might result.

Metal(IV) Phosphonates

A fundamental step in the development of the chemistry of layered phosphates was made in 1978

Figure 11 Schematic representation of the exfoliation of α -Zr(HPO₄)₂·H₂O microcrystals by intercalation of n-propylamine. The formation of completely inorganic films or the coating of solid surfaces is also reported.

Figure 12 Schematic representation of a pillared layered structure showing the microporosity and the diffusion paths.

when the first Zr(IV) phosphonates and Zr(IV) organophosphates with formula $\text{Zr}(\text{RPO}_3)_2$ or $\text{Zr}(\text{ROPO}_3)_2$ respectively, were prepared (R being an organic group). These compounds are organic derivatives of α -Zr(HPO₄)₂·H₂O in which the -OH groups attached to the phosphorous atoms have been replaced by organic R groups, leaving the inorganic structure of the α -layer essentially unchanged.

A further development in layered metal(IV) phosphates was achieved with the resolution of the structure of the γ -phases and with the discovery that it is possible to replace interlayer dihydrogenphosphate groups by monovalent phosphonate or phosphinate anions by simple topotactic anion exchange reactions (see above).

Nowadays, a large number of metal(IV) phosphonates of α - and γ -type are known and many others can be prepared for special purposes, constituting a very large and versatile class of layered materials. A brief account of preparation procedures, structural

Figure 13 Computer-generated representation of the sequence of two layers of α -Zr(C₆H₅PO₃)₂. (Data from Alberti G, Costantino U, Allulli S and Tomassini N (1978) *Journal of Inorganic and Nuclear Chemistry* 40: 1113–1117, with permission from Elsevier Science.)

features and the chemistry of α - and γ -zirconium phosphonates is given.

Zirconium Phosphonates of α -Type

The preparation of Zr phosphonates is closely related to the methods employed for the preparation of α -Zr(HPO₄)₂·H₂O, i.e. refluxing of amorphous precipitates with solutions containing the chosen phosphonic acids, and the direct precipitation method in the presence of Zr fluorocomplexes and the suitable H₂O₃PR acid.

As already mentioned, the layer structure arises from the concatenation of ZrO₆ octahedra and O₃PR tetrahedra similar to that present in α -zirconium phosphate. Due to the short lateral distance between adjacent O₃P–R groups on each side of the α -layer

(5.3 Å) interpenetration of the R-groups belonging to adjacent layers cannot occur for steric reasons and a double film of R-groups is expected for all the members of this class. Therefore these organic derivatives have a layered structure similar to that of zirconium benzenephosphonate (see **Figure 13**) or zirconium carboxyethanphosphonate (see **Figure 14**), two typical compounds of the class.

A list of selected α -layered phosphonates is given in **Table 4**. Note that the compounds contain a variety of functional groups. By choosing appropriate organic groups attached to the phosphorus atom, it is possible to vary the acid properties of the phosphonates from neutral (e.g. P–CH₃) or weakly acid (e.g. P–CH₂COOH) to strongly acid (e.g. P–C₆H₄SO₃H) or even to basic (e.g. P–C₂H₄NH₂), or to anchor the amino acid chiral group. The nature of the covalently

Figure 14 Computer-generated representation of the sequence of two layers of α -Zr(HOOCCH₂CH₂PO₃)₂. (Data from Alberti G, Costantino U, Casciola M, Vivani R and Peraio A (1991) *Solid State Ionics* 46: 61–68, with permission from Elsevier Science.)

attached groups depends on the imagination and ability of the chemist to synthesize the appropriate phosphonic acids.

The only limitation to synthesis is the use of organic groups with a cross-section equal to or less than 24 Å². This is the free area around each P–OH group

present on the surfaces of the layers of the parent α -Zr(HPO₄)₂. However, more voluminous groups may be attached to the α -layers if their dimensions are compensated by introducing small groups R' (R' being H, OH, CH₃) to obtain compounds of formula Zr(RPO₃)_{2-x}(R'PO₃)_x. These mixed component phases are of great interest since a very special type of complexing agent or redox couple may be fixed to the layers. A selection of the multicomponent phases prepared to date is given in Table 5.

Zirconium diphosphonates, of general formula Zr(O₃P–R–PO₃), in which adjacent inorganic layers of the α -type are covalently joined to each other by divalent organic groups, may also be obtained. These zirconium phosphates do not possess interlayer microporosity, because the distance between adjacent pillars is 5.3 Å and the van der Waals diameter of the alkyl or aryl pillar is about 4 Å. It is however possible to create microporosity in the interlayer region if some pillars are replaced by small O₃P–H groups, and if the pillar has been suitably designed. By using a pillar with bases, such as 3,3',5,5'-tetramethylbiphenyl-diphosphonic acid, a pillared compound exhibiting a high phosphite percentage and interlayer microporosity of 375 m² g⁻¹, has recently been prepared.

$\text{Zr}(\text{O}_3\text{PC}_6\text{H}_4\text{SO}_3\text{H})_{0.97}(\text{O}_3\text{PCH}_2\text{OH})_{1.03} \cdot 4.9\text{H}_2\text{O}$	19.6

A computer-generated structural model of this microporous pillared compound is shown in Figure 15.

Zirconium Phosphate Phosphonates of γ -Type

The structure of the γ -layer differs from that of the α -layer since the ZrO_6 octahedra are placed in two different planes and joined to each other by PO_4 tetrahedra. Due to the fact that only three oxygens are available in phosphonate groups, pure γ -zirconium phosphonates cannot exist. However, it is possible to replace the interlayer H_2PO_4 groups by monovalent phosphonate or phosphinate anions to obtain layered inorganic-organic derivatives in which the inorganic layer regularly alternates with organic

layers. These materials are obtained from a simple topotactic reaction by contacting the original zirconium phosphate microcrystals with a solution of a suitable phosphonic acid. As we have already seen this reaction is similar to an anion exchange process. The texture of the γ -layer remains practically unchanged and it is therefore possible to predict the arrangement of the organic groups in the interlayer region by considering the interlayer distance and the dimension of the groups. Figure 16 shows the probable structure of γ -zirconium phosphate benzene-phosphonate.

Many organic derivatives have been prepared with this simple procedure including pillared compounds with regular interlayer porosity obtained by partial replacement of the dihydrogenphosphates with bivalent diphosphonate groups. A selected number of recently prepared compounds is reported in Table 6. Monophosphonic or biphosphonic acids containing crown ethers have also been used for the topotactic reaction and compounds with crown ethers covalently attached to the inorganic layers have been obtained. These materials show promise for interesting applications in ionic or molecular recognition and hence for performing selective separations. The γ -system is thus very versatile and the interlayer region can easily be engineered with a large variety of organic groups to obtain materials for application in several fields including the preparation of new stationary phases for chromatographic separation.

Conclusion

The layered phosphates of polyvalent metals are obtained with different layer structures and exhibit

a rich chemistry. Many of them are inorganic ion exchangers that support the most common organic resins in processes which occur at high temperatures or in the presence of strong oxidizing solutions and

*N-(phosphonoethyl)aza crown; (12)crown-4.

strong doses of ionizing radiation. Furthermore, these inorganic ion exchangers possess a high ion exchange capacity and some peculiar selectivities. Layered phosphates are good intercalating agents of ionic or polar species. This allows the construction in the interlayer region of supramolecular assemblies with special functionalities in the fields of chromatographic supports, chemical and electrochemical sensors, ion exchange membranes, ionic and molecular recognition and catalysts. The delamination of layered phosphates has permitted the preparation of thin films and coatings and pillared layered structures with accessible microporosity. There are many more possibilities in layered phosphonate chemistry because functional groups may be inserted on alkyl chains or on aryl rings. The field of layered phosphates and phosphonates is in continuous expansion and these materials will find many applications as soon as their potential is realized.

Novel Layered Materials: Non-Phosphates

R. Mokaya, University of Cambridge, Cambridge, UK
Copyright © 2000 Academic Press

Introduction

In this paper the structure and composition of layered materials (excluding those which contain phosphates) and their modified variants are described. Layered materials are made up of sheets or planes of atoms held together by interplanar forces which are weaker than intraplanar binding forces. This structural set-up allows the insertion of atomic or molecular guest species between the layers. Such insertion (or intercalation) provides a means for controlled variation of the physical and chemical properties of the host

layered material over wide ranges to yield new variants of novel layered materials. The intercalated layered materials are also described.

Layered materials may be broadly classified into three groups according to the composition of their layers and the forces that hold the layers together. The interlayer forces determine the inherent ability of the layers to resist distortions involving displacements transverse to the layer planes.

1. Type I layered materials are made up of layers of atomically thin sheets. The neutral layers are held together by van der Waals forces. Examples are graphite and boron nitride. In graphite the layers tend to be 'floppy' and are easily separated with respect to distortions transverse to the layer

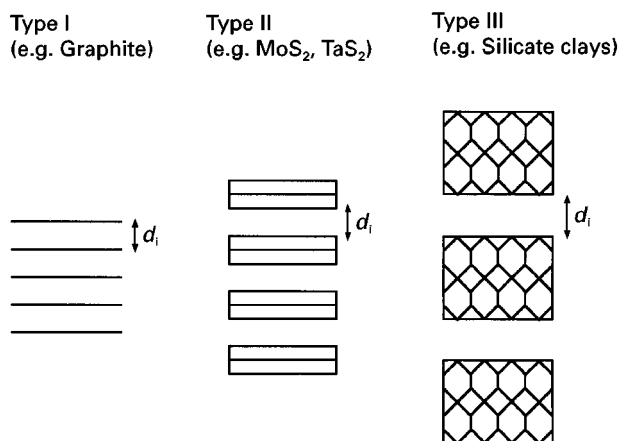

Figure 1 Schematic classification of layered solids (d_i = inter-layer distance).

- planes. Graphite is however rigid against longitudinal in-plane distortions.
2. Type II layered materials, such as dichalcogenides and lamellar oxyhalides, have layers composed of a few (usually three) distinct planes of strongly bonded atoms held together by van der Waals forces.
 3. Type III layered materials have layers made up of dense (up to seven) assemblies of strongly bonded atoms. The layers may be charged in which case the interlayer forces are ionic resulting in layered structures, such as silicate clays and layer double hydroxides, which are quite rigid to interlayer distortion or expansion.

Figure 1 gives a schematic illustration of the three classes of layered materials.

In all cases the intralayer forces are much stronger than the interlayer forces and therefore guest species can be inserted into the interlayer region between the host layers without any change to the layers themselves. This attractive feature of layered materials has been extensively exploited. Indeed, the bidimensional character of many layered materials can be gradually modified by intercalation, grafting, or pillaring with a variety of guest species to yield new classes of novel layered materials. Type I intercalation materials, such as those of graphite, form stages in which n -multilayers of the host are separated by monolayers of guest intercalant to form expanded n -stage materials. Type II materials are able to accept guest species into random interlayer sites and may ultimately form a saturated stage-1 expanded material at sufficient guest species concentrations. In contrast type III materials always form intercalation compounds with a stage 1 stacking sequence in which the host layers are separated by one or more layers of the guest

species. Novel layered materials that have found use in separation processes are mainly (intercalated or otherwise modified) type III materials and this paper is therefore devoted to such materials with only a brief mention of type I and type II intercalated materials (using graphite and dichalcogenides as examples) given below.

Type I: Graphite

Graphite is known to be intercalated by both electron donors and acceptors and to a large extent the driving force for intercalation is electronic in nature. Thus depending on the guest species, positively charged carbon layers or negatively charged carbon layers may be obtained. Graphite intercalation compounds usually exhibit a high degree of ordering and are unique among layered host materials in that the intercalation occurs such that, depending on the extent of guest species incorporation, it is possible to observe the staging phenomenon (**Figure 2**). The staging phenomenon is defined by a periodic arrangement of n graphite layers (where n is the stage index) between sequential intercalant layers. Well staged graphite intercalated materials can be prepared up to $n \sim 10$. Strong interatomic intercalant–intercalant binding relative to the intercalant–graphite binding favours a close-packed in-plane intercalant arrangement and is the driving force for the staging phenomenon. Graphite intercalation compounds (GICs) have found use as catalysts, electric conductors, recording materials (in inks and coloured leads) and as lubricants and low friction coatings.

Type II: Dichalcogenides

Dichalcogenides, sometimes denoted TX_2 , have layers made up of a sheet of metal atoms (T)

Figure 2 The staging phenomenon as exhibited by graphite (for stage 3, d_i = carbon interlayer distance, d_e = intercalate distance and d_r = repeat basal distance).

Figure 3 Schematic illustration of intercalant concentration dependent intercalation of type II layered materials.

sandwiched between two sheets of chalcogen (X) atoms. T is usually a transition metal and X may be S, Se or Te. The layers are largely neutral and separated by a van der Waals gap. As mentioned above, dichalcogenides are able to accept guest species into random interlayer sites and may ultimately form a saturated stage 1 expanded material at sufficient guest species concentrations (Figure 3). During intercalation, the guest species are inserted in the van der Waals gap and in most cases occupy interstitial sites. The intercalation is generally accompanied by charge transfer between the intercalant species and the host layers and therefore intercalation complexes are formed with electron donor species only. Such species include alkali metal atoms, transition metal atoms and organic molecules. The intercalation of metal atoms (especially alkali metal atoms) results in efficient transfer of electrons to the host compound resulting in unique electronic properties. For metal atom intercalation the increase in layer separation is not large but the weak host layer interactions are replaced by strong Coulomb (alkali metal) and covalent (transition metal) interactions yielding a quasi three-dimensional solid. The intercalation of organic molecules results in much larger layer separations. An example is the intercalation of amines in which the orientation of the amines in the van der Waals gap depends on the number of carbon atoms. Short chain amines, such as methylamine, pack parallel to the layers whereas intermediate chain amines (e.g. C_4 – C_9) orient at an angle to the layers with the nitrogen with its lone pair of electrons adjacent to the layer. The angle of inclination generally increases with chain length and for chain lengths $> C_{16}$, the amines are arranged perpendicular to the host layers and form bilayers resulting in layer separations as high as 57 Å for stage 1 intercalation.

Type III: Layer Silicates (Clays) and Layer Double Hydroxides (LDHs)

Nature of Layer Silicates (Clay Minerals)

Clays are by definition fine grained solids with particle size generally $< 2 \mu\text{m}$ and many of their properties result from their small particle size. The layers of clays are formed by condensation of sheets of linked $\text{Si}(\text{O},\text{OH})_4$ tetrahedra with those of linked $\text{M}_{2-3}(\text{OH})_4$ octahedra, where M is a divalent or trivalent cation. A 1 : 1 condensation gives two sheet minerals such as kaolinite with a general layer formula of $\text{M}_{2-3}\text{Si}_2\text{O}_5(\text{OH})_4$. A 2 : 1 condensation results in the octahedral sheet being sandwiched between two sheets of tetrahedra giving the mica type layer structure with a layer formula of $\text{M}_{2-3}\text{Si}_4\text{O}_{10}(\text{OH})_2$. In both cases the tetrahedral sheets are linked in the unit structure to octahedral sheets and to groups of coordinated cations or individual cations. The apical oxygen at the fourth corner of the tetrahedron, which is directed normal or nearly normal to the sheet, forms part of an immediately adjacent octahedral sheet in which octahedra are linked by sharing edges. The junction plane between tetrahedral and octahedral sheets consists of the shared apical oxygens of the tetrahedra and unshared OH groups that lie in projection at the centre of each six-fold ring of tetrahedra. Figure 4 shows a three-dimensional schematic illustration of layer silicates. Also possible, for example in chlorite, are four sheet clays in which the trimorphic units alternate with $\text{M}(\text{OH})_{2-3}$ sheets of octahedrally coordinated M^{2+} or M^{3+} ions.

Smectite clays, which exhibit the property of intercalation, are made up of negatively charged layers and therefore possess an ion exchange capacity which distinguishes them from the mica and pyrophyllite-talc groups of minerals (see below). The layer charge arises generally from isomorphous substitution of Si^{4+} by Al^{3+} in the tetrahedral sheet and/or Al^{3+} by Mg^{2+} , Fe^{2+} in the octahedral sheet. Some charge may also arise from broken bonds at edges of the clay crystal. Following below are ideal structural formulae of some clay silicates showing, where appropriate, isomorphous substitution:

1. Dioctahedral smectites (two-thirds of octahedral sites are occupied by trivalent cations)
 - (a) Pyrophyllite
 $[(\text{Si}_8)(\text{Al}_4)\text{O}_{20}(\text{OH})_4]$ No layer charge.
 - (b) Montmorillonite
 $[\text{M}_x(\text{Si}_8)[\text{Al}_{4-x}\text{Mg}_x]\text{O}_{20}(\text{OH})_4 \cdot n\text{H}_2\text{O}]$ Octahedral substitution.
 - (c) Beidellite
 $[\text{M}_x\text{Si}_{8-x}\text{Al}_x(\text{Al}_4)\text{O}_{20}(\text{OH})_4 \cdot n\text{H}_2\text{O}]$ Tetrahedral substitution.

Figure 4 Three-dimensional illustration of the structure of silicate clays.

2. Trioctahedral smectites (all octahedral sites are occupied by divalent cations)
 - (a) Talc
 $[(\text{Si}_8)(\text{Mg}_6)\text{O}_{20}(\text{OH})_4]$ No layer charge.
 - (b) Hectorite
 $[M_x(\text{Si}_8)(\text{Mg}_{6-x}\text{Li}_x)\text{O}_{20}(\text{OH})_4 \cdot n\text{H}_2\text{O}]$ Octahedral substitution.

Smectite clays can intercalate other compounds in a three component system:

1. Host layer with an overall negative layer charge.
2. Exchangeable intercalates (ions) which compensate for the overall negative charge.
3. Neutral molecules (e.g. water) which occur between the layers and are associated with the interlayer cations and the layers.

Pillared Clays

Pillared clays are usually smectite clay minerals in which the interlayer cations are three-dimensional species which in some cases, after appropriate treatment, are fixed to the layers of the host clay. The shape and size of these cations allows them to function as molecular pillars which keep the layers apart at a fixed distance. The pillaring phenomenon therefore exposes much of the intercrystal basal surfaces for adsorption and molecular sieving purposes. Permanent porosity may be introduced in montmorillonite by replacing the interlayer alkali or alkaline earth cation with a variety of species such as tetraalkylammonium ions, tris-metal chelates, bicyclic amine cations and polymeric oxymetal cations. Clays pillared by oxycations or metal oxides are of greatest interest because they exhibit thermal stability in excess of 500°C and, depending on preparation methods, materials with large pore diameters and surface area (Table 1).

The most extensively studied pillared clays are those containing polymeric hydroxy-aluminium species as the pillaring cation. In this paper such Al pillared clays are used to illustrate the nature and properties generally possessed by metal oxide pillared clays. In the non-calcined so-called precursor pillared clay, layer charge is balanced by the pillaring polycations which in the case of Al pillared clays is the Keggin-like $[\text{Al}_{13}\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}]^{7+}$ ion. On calcination this ion is converted into an oxide with the layer charge balanced by the release of an equivalent number of protons, i.e.

The formation of pillars fixed to the layers of the host clay is dependent on the calcination temperature. In general the basal (0 0 1) spacing of the precursor-Al pillared clay decreases to a fixed value upon

Table 1 Pillar type and corresponding basal spacing and surface area for montmorillonite pillared clays

Pillar type	Basal spacing (Å)	Surface area (m ² g ⁻¹)
Alumina	18–19	250–400
Iron oxide	17–18	~ 280
Chromia	19–21	350–400
Zirconia	18–22	250–300
Titania	18–20; 25–29	300–350
Silica	12–13; 16–20	40–200; 150–400
Silica/alumina	16–19	350–500
Titania/silica	38–40	250–400

heating at 500°C. Heating to temperatures up to 400°C causes some contraction but does not prevent re-expansion of the clay upon exposure to moisture. However, the pillared clay obtained by calcination at 500°C usually shows no tendency to expand. This is because in the temperature range 400–500°C an irreversible contraction in the layer spacing occurs, during which the pillars are held within the host aluminosilicate sheets resulting in cross-linked materials. Therefore the precursor pillaring species dehydroxylates progressively on heating to 400°C, releasing protons which migrate into the clay structure and at 500°C condensation takes place of terminal hydroxy groups present on the polymeric ions with the lattice hydroxy groups on the clay. The oxide pillars formed become linked directly via oxygen to the aluminium and magnesium atoms in the octahedral layer resulting in a rigid cross-linked structure resistant to expansion. These changes are illustrated in Figure 5.

The microstructure of pillared clays is controlled by the wet chemistry of synthesis and, to a large

Figure 5 Schematic description of pillaring. In the case of an alumina pillared clay prepared from Ca-montmorillonite, $d_1 = 14.4 \text{ \AA}$, $d_2 = 20.5 \text{ \AA}$, $d_3 = 19.0 \text{ \AA}$.

extent, the method used to dry the precursor pillared clay. The basal spacing of the pillared clays depends on the age of the pillaring reagent, the degree of hydrolysis (polymerization) of the pillaring reagent, the amount of reactants (i.e. Al/clay ratio) and the temperature of pillaring. Pillaring of clays increases their surface area from as low as $30 \text{ m}^2 \text{ g}^{-1}$ to $500 \text{ m}^2 \text{ g}^{-1}$ (Table 1) and generates a microporous structure similar but less constrained than that of zeolites. The volume created can be used for adsorption purposes; the adsorption characteristics are known to vary with the method employed in drying the pillared clay. Air-dried pillared clays are zeolite-like products which cannot adsorb molecules of kinetic diameter 9.2 \AA (e.g. 1,2,5-triethylbenzene) but can adsorb molecules of kinetic diameter 6.0 \AA . Freeze-dried pillared clays can, however, adsorb appreciable amounts of molecules with kinetic diameter of 10.0 \AA . Freeze-dried pillared clays therefore contain a significant fraction of pore openings $> 10.0 \text{ \AA}$ whereas all the pore openings of air-dried pillared clays are $< 9.0 \text{ \AA}$. This is related to the mechanism of layer aggregation during drying. The aggregation may be face to face (for air-dried materials) or edge to face and edge to edge layer contact for freeze-dried materials. Air-dried pillared clays therefore exhibit long range lamellar order with a regular and relatively narrow pore size distribution while freeze-dried pillared clays, on the other hand, exhibit less lamellar order and a broad pore size range.

Metal oxide pillared clays in general tend to possess pores in both the micropore and mesopore size range. The ratio of micropore to mesopore volume largely depends on the interlayer spacing (pillar height) and the interpillar distance. The interpillar distance may be controlled by varying the ion exchange capacity of the host clay; this in turn determines the number of pillaring polycations required to balance the host layer charge. A low exchange capacity favours a low pillar density and vice versa. The interlayer spacing, on the other hand, may be controlled by varying the pillar type. Figure 6 gives a diagrammatic representation of two common pillar types and Table 1 gives some examples of pillar type and basal spacing for montmorillonite clay.

The porosity of pillared clays may also be varied by combining the pillaring process with other treatments such as competitive ion exchange with monocations or acid activation. Indeed acid activation of clays (see below) prior to pillaring yields a different class of materials, generally referred to as pillared acid-activated clays, with quite distinct properties.

An important characteristic of pillared clays (and clays in general) which is in some cases crucial to their

Figure 6 Diagrammatic illustration of polymeric hydroxy-Al (A) and -Ti (B) pillaring cations.

use in separation processes is that they possess considerable acidity and may be classified as solid acids. For example non-calcined precursor-alumina pillared clay possesses Brønsted acidity which arises through the following mechanisms:

1. Polarization of interlamellar water by initial exchangeable cations not replaced by the hydroxy-Al polycations. This is especially the case if the initial exchangeable cation is acidic.
2. The pillaring polymer may hydrolyse to release protons, i.e.

3. The OH groups of the clay lattice and the pillar may also act as Brønsted acid sites.

However, for a pillared clay calcined at temperatures above 400°C, Brønsted acidity is weaker than Lewis acidity. This is due to the migration of protons from the interlayer region into the layer structure where they neutralize the negative layer charge thus removing some Brønsted acid sites.

Acid activated clays When ‘activatable’ clay minerals are treated in acid, their chemical composition and physical properties are altered. The activation process enhances properties already present in the clay minerals and gives them certain desirable properties with respect to their applicability as adsorbents and catalysts. The clays of choice for acid activation are non-swelling bentonites containing montmorillonite as the major component. In general terms the acid activation of montmorillonites proceeds via the removal of octahedral ions and any isomorphously substituted tetrahedral ions. The changes that take place in an idealized montmorillonite with no isomorphous substitution may be

expressed as:

Layer Double Hydroxides (LDH)

Natural layer double hydroxides (or hydrotalcite-like compounds as they are sometimes called) are, unlike clay minerals, relatively rare. Where they occur they are associated with metamorphic rock formations or saline deposits. The structure of LDHs is very similar to that of brucite, $\text{Mg}(\text{OH})_2$, in which magnesium is octahedrally surrounded by six oxygen atoms in the form of hydroxide with the octahedral units extending to form infinite sheets through edge sharing. If some of the magnesium in the sheets is isomorphously substituted by a higher charge cation such as Al^{3+} , the resulting $\text{Mg}^{2+}-\text{Al}^{3+}-\text{OH}$ layer gains a positive charge. Sorption of an equivalent amount of hydrated anions occurs so as to maintain electrical neutrality; in nature the charge-balancing hydrated anion is usually carbonate. The OH groups of the positively charged brucite-like sheet are linked to the CO_3^{2-} groups either directly (via $\text{OH}-\text{CO}_3-\text{HO}$ linkages) or via intermediate water (i.e. $\text{OH}-\text{H}_2\text{O}-\text{CO}_3-\text{HO}$). The interlayer carbonate anions adopt an orientation parallel to the layers, i.e. they lie flat surrounded by loosely bound water (Figure 7). The resulting natural LDH may exist in either of two dimorphic forms, i.e. as a rhombohedral hydrotalcite or a hexagonal manasseite.

LDHs may be described by the general formula

where M represents a metal cation and X represents an anion. M^{2+} may be Mg^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Zn^{2+} and M^{3+} may be Al^{3+} , Cr^{3+} or Fe^{3+} . M^{2+}/M^{3+} ratios between 1 and 5 are possible but are typically $0.25 \leq x \leq 0.33$ and $0 \leq n \leq 6$. Synthetically there is a wide range of variables such as: (i) different combinations of M^{2+} and M^{3+} ; (ii) different charge balancing anions; (iii) different amounts of interlayer water; and (iv) crystal morphology and size. To form LDHs, the M^{2+} and M^{3+} cations must be of a size that can be contained in

Figure 7 Illustration of the top view of LDH ($\text{Mg}_6\text{Al}(\text{OH})_{16}\text{CO}_3 \cdot 4\text{H}_2\text{O}$) lattice.

the holes (octahedral sites) between the close-packed OH groups in the brucite-like layers. This limits the possibilities to cations of ionic size between 0.5 and 0.8 Å and, in the main, excludes cations such as Be^{2+} (0.35 Å), Ca^{2+} (0.99 Å) and Cd^{2+} (0.97 Å). The formation of LDHs is not, however, limited to $\text{M}^{2+}/\text{M}^{3+}$ cations; it is, for example, possible to incorporate monovalent cations (M^+) such as Li^+ in a Li/Al material, or to have divalent/tetravalent materials such as Co/Ti.

The number of exchangeable anions in LDHs depends on the charge density on the host layers. However there are no particular restrictions on the nature of the anion. Inorganic charge-balancing anions include Cl^- , OH^- , NO_3^- , ClO_4^- and SO_4^{2-} . Organic acids such as adipic, succinic, oxalic, malonic, sebacic and terephthalic may also serve as charge-balancing species. However, as mentioned above, nature favours the carbonate ion which is tenaciously held in the interlayer region due to its relatively high polarizability and synthesis of pure LDHs with other anions requires special preparation procedures (see below). LDHs may undergo swelling in a manner not unlike that of silicate clays. For example sulfate-containing LDH may be solvated with glycol or glycerol. In general swelling of LDHs depends on the nature of the interlayer anion (charge, mass, structure), nature of the solvent (polarity, molecular dimensions) and of course the layer charge.

Pillared Layer Double Hydroxides

Pillared LDHs which possess empty interlayer/inter-pillar space are desirable but unlike pillared clays

are difficult to prepare. The difficulty is largely due to the affinity of the layers for the carbonate anion; if CO_2 is present during synthesis, the carbonate is preferentially incorporated and once in the interlayer it is held tenaciously and not easily replaced. Most of the pillaring strategies employ a CO_2 -free environment and make use of the fact that Cl^- or NO_3^- anions are easier to displace. Thus the Cl^- or NO_3^- LDH is prepared, usually under nitrogen, and these anions are then replaced with larger polyoxometalate anions such as, for example, $\text{V}_{10}\text{O}_{28}^{6-}$, $\text{Ta}_6\text{O}_{18}\text{OH}^{7-}$, $\text{Nb}_6\text{O}_{18}\text{OH}^{7-}$. Another approach has relied on the use of LDH initially synthesized with large intercalated organic anions, for example the terephthalate dianion (Figure 8) as the interlayer species. The organic anion is then displaced by the polyoxometalate species. As in clays, the pillaring of LDHs results in an increase in surface area and pore volume. The increases are however lower than in pillared clays. This is due to the high layer charge in LDHs which leads to a high pillar density which in some cases yields materials in which the pillars are 'stuffed' into the LDH and do not exist as isolated discrete pillars. An example is polyvanadate-intercalated LDH which has a surface area of *ca.* $35 \text{ m}^2 \text{ g}^{-1}$ compared to $25 \text{ m}^2 \text{ g}^{-1}$ for the unpillared material. True pillaring does occur as in the case of $\text{Zn}_2\text{Al}[\alpha\text{-SiV}_3\text{W}_9\text{O}_{40}]$ which exhibits a surface area of $155 \text{ m}^2 \text{ g}^{-1}$.

Applications of Pillared (or Intercalated) Layered Solids

The applications of expanded layered solids (LDHs or clays) are largely due to their large surface area and variation in their chemical and physical properties. These properties may be enhanced by the ability to

Figure 8 Illustration of terephthalate intercalated LDH.

tailor them for specific uses. In general these materials have found use as catalysts, ion exchangers and adsorbents and are also useful in gas and liquid separation processes (where they exhibit molecular sieving properties similar to those of zeolites). Some examples are:

1. Organoclays containing molecules such as $(\text{CH}_3)_4\text{N}^+$ are especially suited for certain separation processes due to their hydrophobic nature and high affinity for certain organic compounds.
2. Clays and their oxide-pillared derivatives have found use as: (i) scavengers for hazardous organics (especially from effluent streams); (ii) selective adsorbents of heavy metals from effluent streams; and (iii) purifiers for edible oils where the clays adsorb compounds such as carotenoids and chlorophyll to give the oil its clear look and taste. Indeed acid activated clays are the industry standard for the decolorizing of oil.
3. LDHs have found use as excellent acid residue scavengers.

Greater use of layered materials in separation processes can be achieved when the materials are used in the form of membranes where they act as ionic and molecular filters or sieves.

Organic Ion Exchangers

Abstract

The definition and some characteristic concepts regarding organic ion exchangers are pointed out. The development of these ion exchangers, beginning with chemically modified natural products and continuing with the synthetic ones, is further presented. A classification of organic ion exchangers is proposed according to several criteria, such as the synthesis method, morphology of the three-dimensional network, their physical shape and the nature of their functional groups.

Of the general characteristics of organic ion exchangers only the exchange capacity and selectivity are briefly discussed.

Preparation and structure – chemical property relationships, and some applications with reference to strong and weak cation and anion exchangers, as well as to chelating ion exchangers – are described in more depth.

Definition

An ion exchanger generally is a solid, insoluble material that contains groups which ionize in aqueous medium.

Organic ion exchangers are three-dimensional covalent networks that contain exchangeable ions associated with fixed acid or basic groups. The term 'ion exchange resins' is also used to describe organic ion exchangers.

The ion exchangers that have fixed acid groups and carry exchangeable cations (usually H^+ or Na^+) are cation exchangers described as in the H form and Na

form, respectively. Those with fixed base groups and exchangeable anions (OH^- or Cl^-) are anion exchangers in the OH form and Cl form, respectively.

In the accepted terminology, the three-dimensional network with the fixed groups is called the matrix or framework and exchangeable ions of opposite sign, which neutralize the fixed ionic groups, are the counter-ions that are responsible for the ion exchange process.

Co-ions are mobile ions having the same sign as the fixed charges of the matrix. In fact, organic ion exchangers are crosslinked polyelectrolytes. Thus, a cation exchanger is an anionic polyelectrolyte while an anion exchanger can be regarded as a cationic polyelectrolyte.

General Aspects

The first organic ion exchanger that found technical application was a chemically modified natural product, namely a sulfonated coal, described in many patents during the 1930s.

Other exchangers were synthesized by sulfonation or phosphorylation of wood, paper, cotton, lignin and tannins, as well as by the crosslinking of pectins with formaldehyde or epichlorhydrin.

In 1935 the discovery by Adams and Holmes of ion exchange properties in the product of a reaction between phenol, or *m*-phenylenediamine, with formaldehyde started the development of synthetic organic ion exchangers. These products have a greater importance than those from a natural organic source and have found much wider technical application because of their greater chemical stability and mechanical strength as well as their very different physical and chemical structures.

Synthetic organic ion exchangers are obtained by the two principal reactions used to produce polymeric materials, namely polycondensation or addition polymerization of a mixture of co-monomers. In polycondensation, incorporation of a trifunctional co-monomer is required while in polymerization the presence of a bifunctional co-monomer is sufficient.

Most commercially available ion exchangers are from polymerization processes which create structures with higher hydrolytic and oxidative stabilities as well as better defined physical features and cross-linkings.

In the case of the polycondensation exchangers, the reaction between a co-monomer that carries base or acid groups and a crosslinking agent (formaldehyde, epichlorohydrine, etc.) is used.

In 1944, D'Alelio found that sulfonated styrene-divinylbenzene copolymers have ion exchange

properties. This finding was the beginning of the polymerization ion exchangers.

These structures are made by the polymerization of a mixture of a monovinyllic monomer with a basic or acidic group and a divinyllic monomer. The achievement of a neutral network, called the precursor or starting material, followed by the introduction of basic or acidic groups by suitable polymer-analogous reactions, is often preferred.

Usually divinylbenzene (DVB) is used as the divinyllic monomer and the quantity added, in terms of the percentage in the mixture of co-monomers, defines the degree of crosslinking of the network, although crosslinking side reactions can occur during the polymer-analogous transformations.

The structures created are called 'conventional' or 'gel'-type ion exchangers and generally have about 8% DVB for crosslinking. This amount is required to achieve a network with both mechanical strength and easy diffusion of exchangeable ions as the exchanger comes into contact with an aqueous phase when swelling of the network occurs.

Meitzner and Oline found that the copolymerization of styrene with DVB in the presence of an appropriate inert compound, called 'diluent' or 'porogene agent', gave a network with significant and measurable physical porosity in the dried state, generally containing internal pores having diameters larger than 3×10^{-9} m. This discovery led to significant progress in the field of synthetic ion exchangers, namely the development of macroporous resins. These exchangers offer the advantage that they can be used with non-aqueous solvents and have much higher sorption rates of ions and non-electrolytes than the conventional gel exchangers.

Polymerization produces exchangers in bead form, with a relatively wide distribution of size, by the suspension polymerization technique. More recently ion exchangers with uniform and controlled bead size have become available.

The polycondensation exchangers often appear as irregular-shaped particles, because they are made by bulk polycondensation followed by grinding of the bulk polymer into smaller particles. However, polycondensation exchangers can also be made in bead form by reverse-phase suspension polycondensation.

Ion exchangers in fibre form are also known, made by chemical modification of natural and synthetic fibres. Ion exchanger fibres have an improved kinetic performance when compared with the same structures in bead form.

Classification

Scheme 1 is a summary of the classification of organic ion exchangers. **Table 1** shows the most used

Scheme 1 Classification of organic ion exchangers.

acid and base functional groups on organic ion exchangers.

Characterization

Ion exchange capacity is the most appropriate characteristic of organic ion exchangers.

The total capacity indicates the number of fixed acidic or basic groups per specified amount of ion exchanger. It can be described as both weight capacity and volume capacity, having as units milliequivalents per gram of dry exchanger (meq g^{-1}) and milliequivalents per cubic centimetre of fully swollen exchanger (meq cm^{-3}), respectively. If not

otherwise stated, the capacity should be reported per gram of H form for a cation exchanger or the Cl form for an anion exchanger in the dry state. This capacity is a constant for the material and does not depend on the experimental conditions.

The effective capacity is the number of exchangeable counter-ions per specified amount of exchanger (the same units are used as above). This capacity depends on the experimental conditions and is lower than total capacity.

Another important characteristic is the selectivity which has a major role in the ion exchange processes. The selectivity is the preference of an ion exchanger for a particular counter-ion over the others, when it is

Table 1 Types of ion exchangers and their functional groups

Type	Name of fixed functional group	Chemical structure of functional group
Cation exchangers		
Strong acid	Aryl sulfonic	$-\text{C}_6\text{H}_5-\text{SO}_3\text{H}$
Weak acid	Carboxylic acid	$-\text{COOH}$
	Phenolic hydroxyl	$-\text{C}_6\text{H}_5-\text{OH}$
Intermediate acid	Phosphonic	$-\text{P}(\text{O})(\text{OH})_2$
	Phosphonous	$-\text{P}(\text{O})\text{H}(\text{OH})$
	Phosphoric	$-\text{O}-\text{P}(\text{O})(\text{OH})_2$
Anion exchangers		
Strong base	Quaternary ammonium	$-\text{N}^+$
	Phosphonium	$-\text{P}^+$
	Sulfonium	$-\text{S}^+$
Weak base	Primary amine	$-\text{NH}_2$
	Secondary amine	$-\text{NHR}$
	Tertiary amine	$-\text{NR}_2$
Amphoteric exchangers	Mixture of acid and base groups	

in contact with an electrolyte solution. The selectivity has various physical causes.

An ion exchanger tends to prefer a counter-ion with higher valence, lower solvation, higher polarizability, stronger interactions with the fixed groups or the matrix, and less participation in complex formation with the co-ions. The selectivity of an ion exchanger is improved by increasing degree of crosslinking and by decreasing solution concentration and temperature.

Types of Synthetic Organic Ion Exchangers

Strong Acid Cation Exchangers

The most important strong acid cation exchangers are those of arylsulfonic acid type.

Polycondensation structures of this type can be obtained as follows:

1. By the sulfonation of a phenol followed by the condensation of the sulfonated product with formaldehyde.
2. By the sulfonation of a preformed phenol-formaldehyde three-dimensional network.

In the first method, the addition of unsulfonated phenol to provide the trifunctionality is essential. The structures created are illustrated in **Figure 1**.

A method for the synthesis of sulfonated condensation exchangers in bead form has been developed using organic solvents as dispersion media. This is an

alternative to the grinding of bulk polymers as previously mentioned.

Most commercially available strong acid cation exchangers are those based on styrene-DVB copolymers with different morphologies of their three-dimensional networks. These products have higher capacities and better durabilities than their polycondensation predecessors. The common method for the production of these structures consists in sulfonation of the styrene-DVB copolymers with sulfonation agents such as sulfuric acid, sulfur trioxide, oleum or chlorosulfonic acid.

From the point of view of the mechanism, the sulfonation is an electrophilic substitution into an aromatic ring whereby the $-\text{SO}_3\text{H}$ group is attached in the *para*-position and a double sulfonation is probably impossible because of steric hindrance due to the polymer chain.

During the sulfonation reactions, crosslinking side reactions take place independent of the sulfonating agent, however chlorosulfonic acid apparently leads to the most crosslinks.

Side crosslinks are due to the inter-chain sulfone bridges that appear by reaction between the already attached $-\text{SO}_3\text{H}$ groups and the unreacted aromatic rings. Intra-chain sulfone bridges also can appear. The chemical structure of a sulfonated styrene-DVB copolymer is illustrated in **Figure 2**.

The pre-swelling with organic solvents of the copolymer beads before sulfonation reduces the number of sulfone bridges.

Figure 1 Preparation of sulfonated phenol-formaldehyde cation exchangers.

Addition to the styrene-DVB mixture of small amounts of a polar monomer, such as acrylonitrile, vinylpyridine, etc., improves the physical properties of the resultant ion exchanger – especially its resistance to osmotic shock because of the more uniform sulfonation reaction.

Sulfonations with the agents previously mentioned show some differences. Thus, reaction with sulfuric acid used the acid itself as a reaction medium hence a considerable excess of reagent is required. Reactions with chlorosulfonic acid or sulfur trioxide may be performed in an organic solvent, thus they need only a small excess of reagent over the stoichiometric quantities.

Sulfonations with the latter reagents take place at lower temperatures than with sulfuric acid which requires a temperature at about 100°C.

Post-sulfonation treatment of the sulfonated products is important to maintain whole beads. This can be achieved by the prevention of the changes that determine swelling, called ‘osmotic shock’, which leads to the disintegration of the beads. The gradual addition of water, or aqueous electrolyte solutions, decreases this deleterious effect.

Macroporous copolymer beads, because of their large internal surface areas, have a higher reactivity towards the sulfonation agents. They also require much lower quantities of organic swelling solvent, and are less susceptible to degradation by osmotic shock, both during preparation and in subsequent usage. In addition, they have a higher oxidation stability than the sulfonated structures of the gel type.

Strong acid cation gel-type exchangers have received major attention because of their utility in

Figure 2 Chemical structure of sulfonated styrene-DVB copolymer-based cation exchanger.

water softening which is their principal use. The equivalent macroporous structures can also be used as catalysts for certain reactions, particularly in non-aqueous media, instead of sulfuric and toluene-4-sulfonic acids. The resin catalysts show some advantages compared to low molecular weight acids, such as in their regeneration and potential reuse.

Because of their very high acidity, the aryl-SO₃H groups are fully ionized throughout the pH domain of aqueous solutions. The very low preference of the sulfonic-type cation exchanger for the H ion requires the use of large quantities of mineral acids for its regeneration to the H form after the exhaustion cycle, especially in water treatment processes.

The strong acid exchanger in its H form participates in ion exchange reactions with bases like NaOH and with alkaline or neutral salts. The latter reaction is called 'salt-splitting'.

Weak Acid Cation Exchangers

The polycondensation exchangers can be prepared by the reaction of salicylic acid, or 1,3,5-resorcylic acid, with formaldehyde. In the former case, the addition of phenol is required because one *ortho*-position is not accessible to the aldehyde.

Several polymerization networks that contain -COOH groups are known. Some structures together with their preparative routes are illustrated in Figure 3. Only those with acrylic networks are commercially available.

Compared with the sulfonic group the -COOH group, has a much lower acidity and is fully ionized only in an alkaline medium as a salt form. The -COOH group also shows a very considerable preference for the H ion, unlike the -SO₃H group. This situation leads to easy regeneration of the weak acid exchangers from salt form to H form using stoichiometric quantities of mineral acids. These exchangers can react only with bases, like NaOH, and alkaline salts; they show a strong preference for Ca and Mg cations. The 'salt-splitting' reactions do not take place in the case of the weak acid cation exchangers.

The acrylic-type exchangers have a higher acidity than the methacrylic ones and can be used for the treatment of hard water containing large quantities of bicarbonates. The methacrylic type is used for special applications, such as the purification of antibiotics, where a mild pH is required.

Strong Base Anion Exchangers

Strong base anion exchangers are known only as polymerization products. Those with quaternary ammonium groups are the most common commercially

available exchangers. Their preparation is performed by the chloromethylation of gel- or macroporous-type styrene-DVB copolymers in bead form, followed by the amination of the chloromethylated copolymers with trimethylamine or dimethylethanolamine leading to the so-called strong base anion exchangers of Types I and II, respectively. Their chemical structures are shown in Figure 4.

Usually the chloromethylation is carried out with monochloromethyl ether, in the presence of a Lewis acid (ZnCl₂, AlCl₃, SnCl₄, etc.) as catalyst. The reaction takes place under mild conditions: temperature about 50°C and reaction times of 5–8 h. Generally, the -CH₂Cl groups are attached to over 90% of the *para*-positions of the styrene aromatic rings, following the chloromethylation of the mono alkylbenzene derivatives.

The main chloromethylation reaction is usually accompanied by a side alkylation reaction between pre-attached -CH₂Cl groups and non-functionalized aromatic rings. Such a side reaction determines inter-chain and/or intra-chain methylene bridges that decrease the amount of -CH₂Cl groups as well as the swelling capacity of the chloromethylated product. The latter aspect is especially prevalent in the case of gel-type copolymers. In most cases, the styrene-DVB macroporous networks show a reduction of their specific area and of the volume of their pores after chloromethylation, but an increase of the average diameter of the pores can be observed.

The use of a large excess of chloromethyl methyl ether or mixtures of chloroform or carbon tetrachloride with the halogenated ether reduces the side reaction.

An alternative route to obtain the chloromethylated styrene-DVB network is via the free-radical polymerization of chloromethylstyrene (vinylbenzyl chloride) with divinylbenzene. The first monomer is a 60 : 40 mixture of *meta*- : *para*-isomers.

The chemical structures of the two crosslinked polystyrene-based chloromethylated compounds or products are illustrated in Figures 5A and B. From these two figures one can see that the chloromethylstyrene-DVB copolymer (Figure 5A) has a more homogeneous chemical structure than the chloromethylated styrene-DVB copolymer (Figure 5B), but the former structure has the drawback of a much higher cost. For this reason chloromethylated styrene-DVB copolymers are chosen as the precursors to polystyrene-based anion exchangers.

Aminations of the chloromethylated styrene-DVB copolymers with trimethylamine and dimethylethanolamine take place easily, because the benzylic chlorine structure has a very high reactivity towards these nucleophilic reagents. Amination is performed

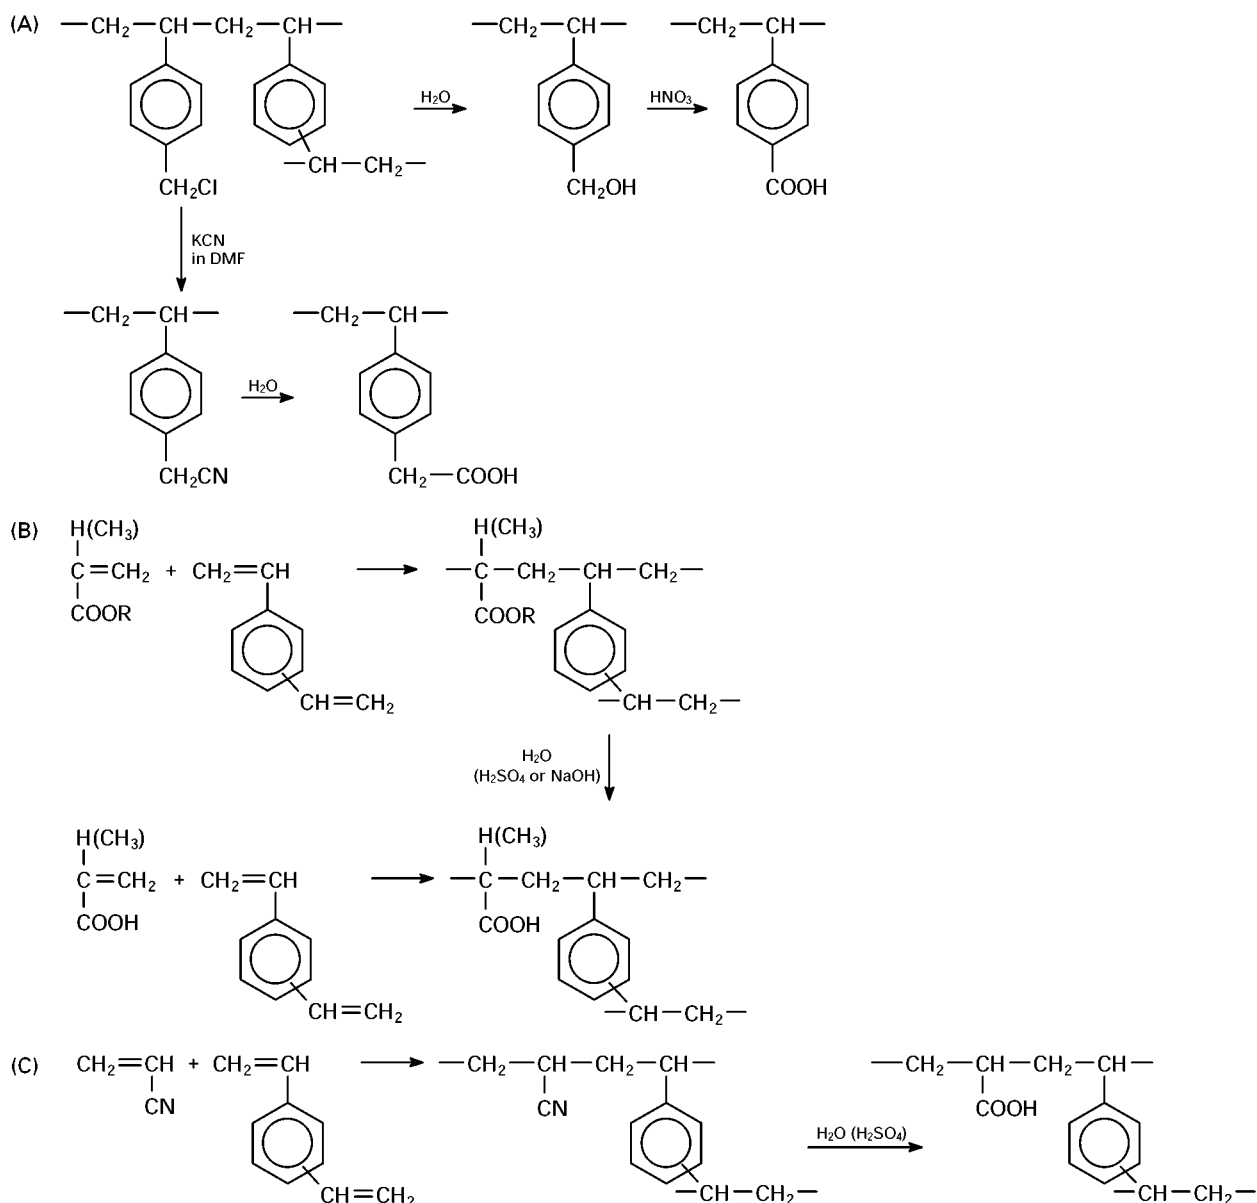

Figure 3 Some methods for the preparation of weak acid cation exchangers.

in organic or aqueous media, at a temperature of about 40–50°C, and reaction times of 6–8 h. It must also be mentioned that amination with the two amines, in contrast to the chloromethylation reaction, does not lead to crosslinking side reactions. When the reactions are carried out in water, a side reaction can occur at a very low level from the hydrolysis of a small number of $\text{—CH}_2\text{Cl}$ groups.

The chemical structures of strong base anion exchangers of Types I and II are not very stable in alkaline media because of the well-known Hofmann degradation, a property of quaternary ammonium compounds; the Type II displays a lower stability in alkaline media than Type I.

Hofmann degradation of the two structures takes place according to **Figure 6**. The degradation can lead to both loss of exchange capacity (routes A and A' in **Figure 6**) and the appearance of a weak base capacity caused by the presence of tertiary amine groups (B, B' and C in **Figure 6**).

Strong base anion exchangers have a lower thermal stability than the cation exchangers.

Other commercially available strong base exchangers are those formed with an acrylic matrix. They are usually made in bead form by free-radical polymerization of 3-dimethylaminopropyl methacrylamide with DVB followed by a quaternization reaction of the copolymer with alkyl halides as shown

Figure 4 Classical structures of the structural units of Type I and Type II strong base anion exchangers.

in Figure 7. For the quaternization, gel- or macroporous-type copolymers can be used.

Generally, the acrylic strong base anion exchangers have a lower stability to hydrolysis, especially under acid or alkaline conditions, compared to the polystyrene-based exchangers. The hydrolysis becomes more significant when the spacer between the amide group and the quaternary group decreases in size. Thus, the product with a spacer of only one methylene group between the two functional groups has hydrolytic instability. The same phenomenon occurs in the anion exchanger prepared from 3-dimethylaminopropyl methacrylate, $\text{CH}_2=\text{C}(\text{CH}_3)\text{COO}(\text{CH}_2)_3\text{N}(\text{CH}_3)_2$, instead of the amide monomer.

In addition to the strong base anion exchangers previously presented as commercially available products, other specialized strong base exchangers are known.

In an effort to develop anion exchangers with preference for the NO_3^- anion over the SO_4^{2-} anion (an important factor for nitrate removal from potable water which invariably contains sulfate), the design of such a structure was conceived. It is the reaction product of the chloromethylated styrene-DVB copolymer with triethylamine, and can be described as a strong base anion exchanger of Type III.

Gel or macroporous 4-vinylpyridine-DVB copolymers are the precursors for strong base

Figure 5 The two crosslinked polystyrene-based chloromethylated structures.

Figure 6 Hofmann degradation of Type I and Type II strong base anion exchangers.

exchangers. These exchangers are made by the well-known quaternization reaction with alkyl halides as shown in **Figure 8**.

The synthesis of this category of anion exchangers takes place by a single chemical transformation step which avoids crosslinking side reactions. However, these exchangers cannot be utilized in many fields of application because of their very low chemical stability in alkaline media.

Ion exchangers with benzyltrialkylphosphonium groups, especially benzyltri-*n*-butylphosphonium halide can be made. These structures are not used in ion exchange processes but have special applications as phase-transfer catalysts. For the improvement of their properties, structures with a spacer larger than one methylene group between the aromatic ring and

the phosphonium group have been synthesized. **Figure 9** shows the phosphonium-type structures and their preparative routes.

Commercially available exchangers of Types I and II are fully ionized in the whole pH domain of the aqueous medium, like the strong acid ones. The Type I exchanger is such a strong base that a considerable quantity of NaOH is required for its regeneration in the OH form, while the Type II exchanger, a weaker base, requires less. This aspect is an advantage of the Type II structure over Type I.

The strong base anion exchangers in their OH form react with both strong and weak acids. With the latter, the strong base anion exchanger of Type I is more effective than Type II. Because of this situation, Type I exchangers are used for soluble and

Figure 7 Preparation of an acrylic strong base anion exchanger.

colloidal silica removal from natural waters. For removal of the colloidal silica only, Type I strong base anion exchangers with special macroporous structures are effective.

Certain Type I strong base exchangers in their Cl form are used for adsorption of ionic organic compounds and are called 'scavenger' ion exchangers.

Weak Base Anion Exchangers

Commercial weak base anion exchangers are prepared by the condensation of *m*-phenylenediamine

with formaldehyde. The chemical structure of this exchanger is illustrated in **Figure 10**. In this structure, the amine groups directly attached to benzene rings have a very low basicity.

Polycondensation weak base exchangers with higher basicity were later obtained by the condensation of other reagents. An example is the epoxy structures formed by the condensation of aliphatic polyamines with epichlorohydrin. This halo-epoxy compound can react even with tertiary amine groups, thus anion exchangers containing amine and quaternary ammonium groups can be obtained as shown in **Figure 11**.

The most readily available commercial weak base exchangers are the polymerization structures based on polystyrene or acrylic matrices containing primary, secondary or tertiary amine groups, or all these groups together.

The polystyrene-based weak base exchangers are obtained by the same reaction scheme as the strong base ones with polystyrene matrices, but with the difference that dimethylamine is used in the amination step instead of trimethylamine or dimethylethanolamine. When using the secondary amine, in contrast with the tertiary amines, besides the main amination reaction which leads to the tertiary amine groups, an undesirable side reaction can also take place. This is the quaternization reaction between the pre-attached tertiary amine and $-\text{CH}_2\text{Cl}$ groups. It can take place intra- or inter-chain but both situations can occur.

The chemical structures of aminated units are shown in **Figure 12**. Both quaternization types (inter- and intra-chain) lead to anion exchangers with mixed

Figure 8 Preparation of strong base anion exchangers based on 4-vinylpyridine-DVB copolymer.

Figure 9 Preparation methods of phosphonium-type strong base anion exchangers.

functional groups and the inter-chain ones also control the degree of crosslinking.

Amination takes place quantitatively under mild conditions (30–40°C; 4–6 h) in aqueous or organic media. By using a large excess of amine, the side quaternization reaction is greatly reduced.

The most common acrylic weak base exchangers are made by the acylation of primary or secondary amines. This reaction with esters, so-called ester

aminolysis, is the most frequently used method to produce acrylic weak base exchangers.

The aminolysis of macroporous or gel-type ethyl acrylate–DVB copolymers, in bead form, with 3-dimethylamino-1-propylamine, ethylenediamine or other aliphatic polyamines, is illustrated in **Figure 13**.

The same structures can also arise from aminolysis–hydrolysis reactions of acrylonitrile–DVB copolymers. An example is shown in **Figure 14**.

Figure 10 Chemical structure of *m*-phenylenediamine–formaldehyde weak base anion exchanger.

Figure 11 Chemical structure of an epoxy-type base anion exchanger.

The aminolysis and aminolysis-hydrolysis reactions take place under more stringent reaction conditions (temperature over 100°C and reaction time over 10 h) than the amination of the chloromethylated styrene-DVB copolymers.

Acrylic weak base exchangers synthesized from aliphatic polyamines have much higher exchange capacities than polystyrene-based structures.

The weak base exchangers cannot be regarded as typical ionic polymers since their amine groups are ionized only under certain conditions. Thus, an amine group in an alkaline medium is in the free-base form, but in a neutral medium it can exist in a partial ionization level, which depends upon amine basicity.

In an acid medium a high level of ionization is present and because of this, the weak base exchangers are usually used to retain strong acids in water treatment. They also can be used as insoluble acceptors of acids in different chemical reactions such as the preparation of esters from acid chlorides and alcohols, etc. For the latter aim, the best known are the 4-vinylpyridine-DVB copolymers with a low degree of crosslinking.

Scheme 2 shows some more distinctive ion exchange reactions for the four above-mentioned types of exchangers.

Amphoteric Ion Exchangers

Ion exchangers which contain both acidic and basic groups are called amphoteric resins. Usually their matrix has some structural units with acidic groups and other units with basic groups.

Very interesting amphoteric resins are the so-called 'snake-cage polyelectrolytes'. One feature distinguishes the snake-cage polyelectrolytes from other amphoteric resins, namely the acidic and basic groups are not attached to the same matrix. For example, a snake-cage polyelectrolyte is prepared by polymerization of acrylic acid (snake) into a strong base anion exchanger with quaternary ammonium groups (cage). These resins are excellent reversible sorbents for electrolytes and can be regenerated by rinsing with water. Electrolyte sorption seems to be mainly determined by the preference of the acidic groups for the cation and of the basic groups for the anion. The resins show preference for different electrolytes. This phenomenon can be used for separating electrolytes one from another.

Figure 12 Chemical structure of the functional groups which can exist in a polystyrene-based weak base anion exchanger.

Figure 13 Acrylic-type weak base anion exchangers and their preparation methods.

The snake-cage polyelectrolytes are also used in the technique of 'ion retardation'. This technique is the separation of strong electrolytes from weak electrolytes or non-electrolytes.

Chelating Ion Exchangers

The cation binding of transition, heavy and noble metals can be performed by an ion exchange process

with strong and weak acid cation exchangers as well as with strong base exchangers; the latter are used if the metal cations are present in the form of complex anions.

However, the most promising technique for the binding of metal cations is the use of ion exchangers which contain chelating functional groups. Thus, exchangers with iminodiacetate groups can remove several ppm of Ca^{2+} , Mg^{2+} or Sr^{2+} from brine, in contrast to cation exchangers containing the

Table 2 Some chelating acid and base functional groups

Functional group	Chemical structure	Utilizations
Amine	$-\text{NH}-(\text{C}_2\text{H}_4-\text{NH})_x-\text{H}$	Removal of transitional metals
Iminodiacetic	$-\text{N}-(\text{CH}_2-\text{COOH})_2$	Selective removal of heavy metals
Isothiouonium	$-\text{S}-\text{C}(\text{NH}_2) = \text{NH}$	Selective removal of mercury and noble metals
Aminophosphonic	$-\text{CH}_2-\text{NH}-\text{CH}_2-\text{P}(\text{O})(\text{OH})_2$	Especially for decalcification of brine solutions
Phosphonic acid	$-\text{P}(\text{O})(\text{OH})_2$	Preconcentration of uranyl ions
Hydroxamic acid	$-\text{CO}-\text{NHOH}$	Selective retention for Fe(III) ions
Hydroxyamine	$-\text{CH}_2-\text{N}(\text{CH}_3)-\text{CH}_2-(\text{CHOH})_4\text{CH}_2\text{OH}$	Selective retention for boric acid

Figure 15 Classical binding of metal cations by some chelating functional groups. (P is a polymer structure unit that contains an acid or base group.)

non-chelating common acid groups. The latter exchangers show a higher selectivity for divalent cations than for Na^+ , but the difference is not very large, so that they will not be able to bind Ca^{2+} , Mg^{2+} or Sr^{2+} cations present at very low concentrations.

The high selectivity of chelating ion exchangers is attributed to the establishment of much stronger bonds than the simple electrostatic attractive forces present in the case of the common ion exchangers. Because of these bonds, the chelating processes show a high degree of irreversibility.

It must be mentioned that the chelating groups, attached to polymer networks, are groups with two or more electron donor elements, such as N, S, O and P, and they can function like the model low molecular weight chelating agents. Their preparation takes place in two main ways – polymerization or polycondensation.

Table 2 shows some functional groups, which are capable of chelating. The binding of metal cations by some chelating functional groups is illustrated in Figure 15.

The nature of metal cation binding can be modified by changing the pH of the solution to cause chemical modification of the chelating groups. Thus,

amine and isothiuronium groups can take part in the equilibria, shown in **Figure 16**. These groups will bind metal cations by a coordination process in neutral or base media via the free base forms while in an acid medium the same cations will be bound as complex anions by an anion exchange process via the salt forms.

Conclusions

The area of organic ion exchangers remains a very active one with intensive technical and scientific work on both conventional resins and entirely novel systems. Thus, organic ion exchangers with different morphologies of their three-dimensional networks and base and acid groups with various chemical structures have been prepared.

There is also a growing interest in the development of selective chelating ion exchangers for the possible application of these resins in analytical chemistry, metal recovery and wastewater treatment. The latter two applications have a great importance in economic and ecological domains. Requirements of the properties of these ion exchangers include high capacity, high selectivity and fast kinetics. Most of the

Figure 16 Chemical structure dependence of amine and isothiuronium groups on the pH of aqueous medium.

commercial resins show a high capacity but a poor selectivity towards metal ions.

The combination of the physical strength of an inorganic support with the higher ion exchange capacity and kinetics of the organic ion exchangers could, in the future, lead to an interesting class of ion exchangers with special applications.

Organic Membranes

Toruń, Poland

Copyright © 2000 Academic Press

Organic ion exchange membranes are made of insoluble polymeric foils, tubes or hollow fibres to which ion exchange groups are covalently bound. The membranes have all the properties typical of ion exchange resins and the ability to keep two different solutions physically separated. Thus, the main property of an ion exchange membrane is a selective exchange of ions and a selective permeability to ions, water or other specifically membrane-soluble species. Although optimizing all the properties would be difficult in the case of one membrane used for a variety of applications, the most desired property is always high membrane selectivity, which allows the separation of ions with low energy consumption and high transport rates. There are many additional requirements for ion exchange membranes, such as low electric resistance, high permselectivity, low free diffusion of salts (leakage), low osmotic water transport, high mechanical strength, high selectivity between ions of the same charge and high chemical stability.

Preparation

Ion exchange membranes can be classified as monopolar or bipolar. In parallel, some intermediate mem-

branes have been categorized as mosaic and amphoteric. The monopolar membranes can be divided into cation exchange membranes and anion exchange membranes. Combination of these membranes results in a bipolar ion exchange membrane.

The properties of any ion exchange membrane are determined by the properties of its polymer matrix and the type and concentration of the fixed ionic moieties. The polymer matrix of ion exchange membranes is usually cross-linked. The degree of cross-linking extensively influences the degree of swelling (water sorption), chemical and mechanical stability and membrane permeability by changing ionic mobility inside the membrane phase. Thus, the proper selection of membrane components, their content and the method of preparation significantly affect the membrane properties and structure. The subsequent chemical modification of the polymer matrix involves the introduction of ionogenic groups, resulting typically in the following fixed sites:

Cation exchange membranes:

Anion exchange membranes:

Monopolar Membranes

The simplest ion exchange membranes are composed of derivatives of styrene-divinylbenzene copolymers or vinylpyridine-divinylbenzene copolymers. In order to maintain their mechanical strength, these homogeneous membranes are often reinforced by backing materials. Other simple ion exchange membranes can be synthesized from finely powdered ion exchange resin and inert polymer powder applied as a bonding material. Nowadays, more advanced methods of membrane preparation are recommended. The most widely used methods are:

1. Impregnation of a basic polymer component with styrene and divinylbenzene for copolymerization followed by chemical modification (e.g. sulfonation);
2. Casting the mixed solution of poly(styrene sulfonic) acid and other inert polymer to produce an interpolymer or 'snake-in-cage' membrane;
3. Radiation grafting of a polymerizable monomer into a conventional polymer film and then introducing the ion exchange groups to the film. The films used are generally polyethylene, polypropylene and perfluoroethylene;
4. Chemical modification: this method involves direct introduction of ion exchange groups to a condensation-type polymer such as polysulfone, poly(ethylene oxide), poly(vinyl chloride), poly(vinylidene fluoride), poly(ether ether ketone). The membrane can be formed subsequently by casting the polymer solution, and then phase inversion. The procedure results in an anisotropic membrane structure with a thin skin layer and a supporting layer of sponge morphology;
5. Plasma polymerization. This relatively new method has been utilized to prepare: first, an anion exchange membrane by plasma polymerization of γ -aminopropylethoxydimethylsilane on a porous polymer film; second, a perfluorocarbon sulfonic acid membrane, by plasma polymerization of perfluorostyrene and SO_2 ; and third, a thin film sulfonic-type membrane, by plasma polymerization of ethylene and SO_2 , or acetylene and SO_2 .

Bipolar and Mosaic Membranes

Preparation methods of bipolar ion exchange membranes involve the introduction of cation exchange groups into one side of the membrane and anion exchange groups into the other side. In order to obtain the simplest bipolar membrane a separate cation exchange membrane and an anion exchange membrane can be glued together by using poly(styrene

sulfonic) acid as a binder. Other bipolar ion exchange membranes have been prepared by graft polymerization of acrylic acid on one side of the porous polymer membrane and of *N*-(2-methacryloyloxyethyl)-*N,N,N*-trimethylammonium chloride on the other side, after oxygen plasma treatment of the porous membrane. The mosaic membranes are usually prepared by casting a multiblock copolymer composed of styrene, butadiene and vinylbenzyl dimethylamine and the subsequent introduction of cation and anion exchange groups into the polymer.

Structure

The properties of ion exchange membranes depend on their microstructure, which results from the differences in properties of their ionic and neutral components. The hydrocarbon ion exchange membranes are generally composed of derivatives of styrene-divinylbenzene copolymer and other inert polymers such as polyethylene and poly(vinyl chloride). Ionic derivatives of such copolymers are finely distributed in the inert polymer-forming microdomains because of their poor mutual compatibility. This inhomogeneity causes the distribution of ion exchange groups in the membrane material to be of varied local concentration. The local distribution of fixed charges can affect all the basic membrane properties, such as electrolyte sorption, electrical conductivity and permselectivity as well as mass transport rates. Specifically, a rather unusual structure is characteristic for perfluorocarbon cation exchange membranes (with sulfonic or carboxylic acid groups), which can be classified as ionomer materials. Ionomers and ion-containing polymers with ionic sites and counterions spontaneously organized into dipole multiplets and, for some materials, into larger ion clusters containing 50 or more pairs of ions. These clusters are embedded in the perfluorocarbon membrane backbone, and are connected by narrow channels forming a continuous network.

Despite the heterogeneity resulting from the hydrophilic and hydrophobic nature of membrane components, certain additional morphology features originate from the method of preparation. So-called macroscopically homogeneous membranes can be prepared either by the polymerization of functionalized monomers or by careful modification of a homogeneous polymer film. However, depending on the method of preparation, the structural imperfection of membranes increases in the following order: interpolymer membranes, graft and block polymer membranes and membranes composed of powdered ion exchange resins embedded thereafter in an inert polymer binder.

General Physicochemical Properties

Ion exchange membranes are characterized by many of the parameters and properties described below. Independently, the basic properties describing equilibrium and transport properties of any membrane are as follows: ion exchange capacity (mol kg^{-1} of dried membrane), swelling ($\text{wt.}\%$ of water or other solvent), electrolyte sorption (mol kg^{-1} of water sorbed into membrane), distribution coefficient (ratio of solute concentration in the membrane and external solution), transference number for cations and anions (determined under standard conditions), electrical conductivity (or resistivity) and salt leakage (both determined after contacting the membrane with a standard electrolyte solution).

Co-ion Exclusion

In a cation exchange membrane, due to the system electroneutrality, the fixed anions are in equilibrium with mobile cations (referred to as counterions). In contrast, anions functioning as co-ions are more or less excluded from the membrane because their charge is identical to the fixed ion charge. This phenomenon, known as the Donnan exclusion of co-ions or electrolytes, enables the ideal membrane to transfer cations only. In the same way cations are excluded from the anion exchange membrane. The Donnan exclusion equilibrium, and thus the membrane selectivity, depends quantitatively on the concentration of the fixed ions, the valence of co- and counterions, the concentration of an equilibrating external solution, and the affinity of the exchange groups to respective counterions.

Transport Processes

The effectiveness of any membrane process is determined by the flux of species through the membrane. High fluxes arise because of high permeability of the internal aqueous membrane solution in respect to sorbed solutes. The presence and properties of transport-mediating functional ionic groups can either facilitate or hinder transport processes depending on many specific interactions between mobile species, the charged polyelectrolyte network and solvent. In general, membrane transport phenomena can be described by a general equation derived from the linear thermodynamics of irreversible processes:

$$J_i = \sum_k L_{i,k} X_k \quad (i, k = 1, 2, 3, \dots, m)$$

where J_i denotes the flux of an individual permeant, the volume of solvent, heat or electricity transferred across a membrane, and $X_{i,k}$ denotes the driving force

represented by a difference in chemical potential ($\Delta\mu$), temperature (ΔT), pressure (Δp) or chemical affinity (A). $L_{i,k}$ is the phenomenological coefficient linearly relating the flux and driving force. In practice, a general flux equation can be reduced to a description of a specific process by neglecting coupling transport phenomena. Depending on the solution and assumptions, various mathematical relations have been derived and applied to discuss transport rates of ionic substances and water through ion exchange membranes.

Permselectivity

The characteristic property of ion exchange membranes is their ionic permselectivity related to electrically driven processes and quantified by the following definitions:

$$P_{\text{CEM}} = \frac{t_{+, \text{CEM}} - t_{+}}{t_{-}} \quad \text{and} \quad P_{\text{AEM}} = \frac{t_{-, \text{AEM}} - t_{-}}{t_{+}}$$

where t is the transference number for anions ($-$) and ($+$) cations in free electrolyte or acting as counterions (cation exchange membrane (CEM) and anion exchange membrane (AEM)) in an ion exchange membrane. An ideal permselective membrane should have a P value of 1, and the permselectivity is equal to zero when the transference numbers within the membrane are the same as in an electrolyte solution. Usually, transference numbers for practical membranes attain values from 0.8 to 0.98.

Separation Ability

One of the most important uses of ion exchange membranes is the selective separation of solutes. This can be performed because of the differences in the rates at which solutes permeate through the membrane. The size of this difference depends on the separation system, i.e. on the composition of feed solution and the membrane. The criterion of separation is that the composition of the mixture emerging from the membrane cell should be different from that entering on the feed side. Consequently, the separation factor α_B^A measures the extent of selective transport of A in relation to B :

$$\alpha_B^A = \frac{J_A X_B}{J_B X_A}$$

where J_A and J_B are the fluxes (transport rates expressed as numbers of moles issuing from the membrane per unit area and time) and X_A and X_B are the mole fraction of A and B in the feed.

Membrane Processes and Applications

Many applications of ion exchange membranes in transport and separation processes have been made. Although the driving force for ions and water to penetrate through the membrane initially is primarily an electrochemical and chemical potential, it has been reported in recent years that the hydraulic permeability, temperature difference and difference in proton concentration can also be exploited. This results in some sophisticated transport mechanisms, the backgrounds and practice of which are reviewed below. The latest applications are due to developments in ion exchange membrane composition and structure. Ion exchange membranes with specific properties have been produced to meet many industrial requirements. For example, the following membranes of specific properties have been developed and commercialized: perfluorocarbon anion exchange membranes for high temperature usage and chemical stability in corrosive media, anion exchange membranes for diffusion dialysis (treatment of corrosive acidic waste waters), anion exchange membranes of high acid retention (electrodialytic concentration of dilute acids), hydrogen ion permselective cation exchange membranes (efficient electrodialysis) and monovalent cation or monovalent anion permselective membranes.

Diffusion Dialysis

Diffusion dialysis results from the difference in rates of permeation of salts and acids through anion exchange membranes. According to the scheme shown in Figure 1, this membrane allows the selective transport of anions across the membrane, ideally remaining impermeable to cations other than protons. Diffusion dialysis has been exploited to remove acids from

Figure 1 Scheme of diffusion dialysis of salt and acid through anion exchange membrane (AEM).

solutions containing different cation species. High quality anion exchange membranes allow this method to be applied to the recovery of sulfuric and other acids from waste solutions generated in steel, metal-refining and electroplating industries.

Donnan Dialysis

Donnan dialysis, also referred to as ion exchange dialysis, occurs after placing an ion exchange membrane between two solutions containing different electrolytes. According to the scheme depicted in Figure 2, ions can cross a membrane when their sign is opposite to the sign of the membrane-forming polyelectrolyte. At the same time, the permeation of co-ions is hindered because of their electrostatic exclusion from the membrane phase. Usually, divalent or univalent metal cations are transported from the dilute feed solution into the highly acidic stripping solution. The coupling of fluxes in this membrane system makes it possible to reach a stable flux of cations from dilute to concentrate phase. Thus, uphill transport (chemical pumping) arises as a result of the interdiffusion of different counterions.

The final distribution of ions between two membrane-adjacent solutions corresponds to the Donnan equilibrium principle, which in the typical case of M^{z+}/H^+ Donnan dialysis, takes the following form:

$$C_{M,s} = k C_{M,f} \left(\frac{C_{H,s}}{C_{H,f}} \right)^{Z_M}$$

Figure 2 Scheme of Donnan dialysis of M^+ and H^+ cations through exchange membrane (CEM). (From Wódzki R, Szczepański P and Pawłowski M (1999) Recovery of metals from electroplating waste solutions and sludge. Comparison of Donnan dialysis and pertraction technique. *Polish Journal of Environmental Studies* 8(2): 111–124.)

Figure 3 Scheme of neutralization dialysis of M^+ cations and A^- anions through cation (CEM) and anion exchange membranes (AEM).

Consequently, when the initial concentration (C) of metal ions (M) in the feed (f) is much lower than the concentration of counter-transported protons (H) in the stripping solution, it is possible to attain substantial enrichment of metal ions in the receiver, or alternatively, almost complete removal of these cations from the feed. Despite the many advantages, only a pilot dialyser for the nuclear industry (recovery of ^{134}Cs , ^{90}Sr and concentration of uranyl ions) has been reported as large scale implementation of this technique. On the other hand, Donnan dialysis is widely used in analytical laboratories as an efficient method for the preconcentration and separation of various cations and anions or for the treatment of complex matrices before analysis.

Neutralization Dialysis

Neutralization dialysis is a membrane process based on the coupling of two simultaneously occurring Donnan dialyses. According to the scheme shown in **Figure 3**, in this case a salt solution is separated from an external acidic and basic solution with a cation and anion exchange membrane, respectively. Protons and hydroxide ions permeate into the desalination compartment by the Donnan dialysis mechanism, which generates the counter-flow of other cations and anions. Under ideal conditions, i.e. without salt leakage and with balanced fluxes of protons and hydroxide ions, the overall process results in almost complete desalination of the internal solution. The practical use of neutralization dialysis for the demineralization of mixtures containing some organic substances (mono-, oligo- and polysaccharides) and polyelectrolytes is recommended.

Pervaporation

In pervaporation processes the application of ion exchange membranes instead of inert polymer mem-

branes is possible. During this process (**Figure 4**) an ion exchange membrane is kept in contact with a stream of the mixture of water and miscible organic solvent, whereas the second side of the membrane is kept under vacuum. Due to the strong affinity of ionic sites to water and an inertness of the polymer backbone to an organic component, water can permeate through the membrane. Thus, the permeation of water can be optimized by changing the membrane polymer, the type and content of the membrane-forming polyelectrolyte (ionomer, cross-linked copolymer, etc.), and the kind of counterions. For instance, cation and anion exchange membranes of various ionic forms have been examined for the separation of alcohol–water and pyridine–water mixtures.

Fixed-site Mediated or Carrier Transport

Analogous to liquid membrane transport mediated by the mobile carriers, ion exchange sites can be exploited as fixed carrier centres in the polymer membrane phase. The membranes exhibiting such a function are referred as fixed-site carrier membranes or reactive membranes. In general, transport phenomena in such membranes are believed to occur as a sequence of exchange reactions between permeating solute and reactive groups located along the polymer

Figure 4 Scheme of water pervaporation through ion exchange membrane (IEM).

chain rather than by pure diffusion phenomena. To be effective the transport mechanism requires fixed sites to be mobile over a certain restricted area. Moreover, their concentration should exceed a certain concentration, enabling instantaneous overlapping of loaded and unloaded centres. Despite many difficulties in understanding and in the theoretical description of this type of membrane transport and separation, a number of processes have been developed. The most interesting are processes dealing with the separation of gaseous substances (CO_2), olefins and sugars. For example, a cation exchange membrane exchanged with ethylenediamine is selectively permeable to CO_2 (from a feed containing CH_4 and H_2S). On the other hand, silver ions exchanged with a cation exchange membrane form an Ag^+ -olefin complex in the membrane phase. Carrier transport of 1-hexene and 1,5-hexadiene from a decane phase through a cation exchange membrane impregnated with silver ions has been reported. Similarly, styrene permeates selectively (compared with ethylbenzene) through the Ag^+ form of cation exchange membrane. A selective transport of sugars via complexation with borate ions fixed in an anion exchange membrane has been performed and referred as carrier-relay transport. In this way, the selective transport of D-glucose, D-xylose, D-arabinose, D-mannose, D-galactose, D-fructose, L-sorbose, sucrose and D-lactose can be achieved.

Membrane Extraction-Hybrid Membrane Systems

The combinations of liquid membrane extraction (usually mediated by specific ion exchange extractant/carrier) with ion exchange membranes in some

relatively new membrane systems have been called membrane hybrid systems (MHS). The scheme of cation transport in a simple MHS is depicted in Figure 5. The MHS operation involves a series of ion exchange-diffusion processes (ion exchange membrane) as well as permeation through a liquid membrane. The presence of an ion exchange membrane at a particular interface stabilizes the liquid membrane and enhances the interfacial ion exchange reactions because of high, and specific, sorption of certain ions by the membrane polyelectrolyte. The long term and stable operation of a liquid membrane system can be achieved with the MHS idea. The selective and active transport of metal cations, inorganic anions and some carboxylic acids has been reported. It is worth noting that these systems can be regarded as biomimetic, which means that they correspond to a cellular envelope of Gram-positive bacteria composed of an ion exchange polymer membrane (cell wall) and a quasi-liquid membrane (cytoplasmic membrane).

Membrane Permeation Coupled to External Reaction

It is possible to accelerate chemical reactions by removing some products from the reaction medium before the reaction reaches its equilibrium state. Ion exchange membranes are effective in these cases. For example, fermentation processes producing ionic materials such as acetic acid can be carried out continuously as an extractive fermentation by removing the products by means of diffusion dialysis, pervaporation or electrodialysis. Ion exchange membranes can be applied to improve the kinetics of chemical reactions by the pervaporative removal of water from the reaction medium. Such a technique has been demonstrated for esterification of oleic acid with ethanol and of propionic acid with isopropanol or propanol.

In more advanced systems, membrane transport phenomena are coupled with enzyme reactions. The most representative system is composed of a cation exchange membrane layer, a porous membrane layer containing entrapped urease and an anion exchange membrane layer. Urea is decomposed into NH_4^+ and CO_3^{2-} in the enzyme layer and products permeate through the respective membrane layers without application of an electric field. A similar idea is utilized in many enzymatic membrane sensors.

Figure 5 Scheme of membrane hybrid system composed of two cation exchange membranes and the liquid membrane containing an ionic carrier (C). Coupled countertransport of M^+ and H^+ cations. (From Wódzki R, Szczepański P and Pawłowski M (1999) Recovery of metals from electroplating waste solutions and sludge. Comparison of Donnan dialysis and pertraction technique. *Polish Journal of Environmental Studies* 8(2): 111–124.)

Ion-Exchange Membrane Separators in Power Sources, Sensors and Electrodes

A typical example is the use of an ion exchange membrane as a solid polyelectrolyte for a fuel

cell. The composite, in which anode catalyst, poly(fluorocarbon sulfonate) cation exchange membrane and cathode catalyst are combined, has been used for hydrogen-oxygen fuel cells. The only product of this cell is water, which seems to be desirable from an ecological point of view. Methanol has also been reported for the generation of electricity and utilizable industrial chemicals by the use of a membrane-containing fuel cell. Various applications of ion exchange membranes of low electrical resistance in alkali batteries are possible. Modern cation exchange membranes made of acrylic acid grafted onto polyethylene film are widely used as separators in alkaline batteries, such as a Ni-Cd secondary battery.

Water content of the ion exchange membranes and thus their physicochemical properties changes with humidity. Therefore, ion exchange membranes are usable as a working part of a hygrometer. When water content of the membrane increases with increasing humidity, the increase in the current or ionic conductivity between the electrodes on both sides of the membrane can be measured and calibrated.

The concentration of alcohol can be indirectly determined by means of a membrane with fixed alcohol-dehydrogenase or alcohol-oxylase. It has been reported that these sensors operate accurately in acidic media after coating the enzyme-fixed membrane by a cation exchange membrane (organic acids cannot approach the enzyme membrane). A similar concept is used for constructing *in vivo* operating sensors for glucose presence and concentration. Some modified electrodes are constructed by coating classic electrodes with layered ion exchange materials. A typical example is the perfluorocarbon cation exchange membrane-coated electrode to control the permeability of redox species such as $\text{Ru}(\text{bpy})_3\text{Cl}_3$ or 1,1-dihydroxymethylferrocene.

Industrial Applications

Membrane Electrodialysis

The basic principle of membrane electrodialysis is presented in Figure 6. The membranes are arranged in a series of anion and cation exchange membranes placed between an anode and a cathode. The cations migrating towards the cathode permeate the negatively charged cation exchange membrane and are retained by anion exchange membranes. The anions are transported in the opposite direction. The final result is an increase in ion concentration and ion depletion in alternate compartments. Membrane electrodialysis has been developed within the last several years, mainly for desalting brackish waters and concentrating brine from seawater. Nowadays,

Figure 6 Basic idea of membrane electrodialysis.

electrodialysis is widely applied in environmental protection (depolluting and recycling of chemicals), in bio-industries (food, pharmacy and biotechnology) and in the treatment of drinking water. Some of these new applications have led to substantial improvements in membrane quality. For instance, special membranes with low permeability to the divalent ions in respect to the monovalent ones, membranes with very low permeability to hydroxyl ions or very low permeability to protons, are currently produced.

Membrane Electrolysis

A typical example of this kind of application is the membrane electrolysis of sodium chloride to produce chlorine, hydrogen and sodium hydroxide (membrane chlor-alkali process). A schematic diagram for this process is presented in Figure 7. Perfluorocarbon cation exchange membranes for chlor-alkali processes should have an anisotropic structure in their cross-section. The cathode side of the membrane has a thin layer of carboxylic acid groups of a given ion exchange capacity, and the anode side of the membrane has a thick sulfonic acid group layer or a carboxylic acid group layer of high ion exchange capacity. Ion exchange membranes can also be applied for the electrodialysis of water to produce hydrogen and oxygen. The technology exploiting a solid polymer electrolyte method is efficient when perfluorocarbon cation exchange membranes are used in the form of a stack with catalytic electrodes covering the membrane surfaces. Ion exchange membranes are also used as separators in organic synthesis by electrolysis. A typical example is the hydrodimerization of acrylonitrile to produce adiponitrile.

Conclusion

The technique of membrane separation can be considered as an energy-saving method because, in

Figure 7 Chlor-alkali process (membrane electrolysis) using a cation exchange membrane (CEM).

general, it does not cause phase conversion. From this point of view, ion exchange membranes and their application technology are one of the most advanced methods enabling the embodiment of closed-loop chemical processes. As solid polyelectrolytes, the membranes are easy to regenerate, recycle and/or promote continuous usage to improve industrial processes. Environmental benefits can be achieved as well.

Since the use of ion exchange membranes has become very diverse, the requirements for membranes with new properties will increase. These requirements should result in the development of new highly functionalized ion exchange membranes. Photosynthetic membranes, biomimetic membranes, complex and specialized membrane sensors, polymerized phospholipids and polymerized crown ethers with ionic groups can be considered as new possible areas of membrane science development.

Introduction

Inorganic and organic ion exchangers consist of either a crystalline or a polymeric matrix and functional groups. Depending on the pH value of the liquid phase, these groups can either be protonated or dissociated. By this means exchangers are able to interact with ions from the liquid phase. There is a large variety of such interactions: they may be due to electrostatic and van der Waals forces, heteropolar and covalent binding, or coordination forces. The resulting sorption phenomena take place at the inner pores and/or surface of the exchangers.

The surface charge generates an electric potential normal to the surface. Consideration of the resulting electrostatic interactions has led to several theoretical descriptions, e.g. the Helmholtz, Gouy–Chapman and Stern models. Modern theoretical approaches consider the adsorption of counterions as a result of chemical interactions between the surface groups and dissolved species. Sorption of protons or of any other kind of ion is treated as a local equilibrium reaction. Specific (for protons and hydroxyl ions) and non-specific interactions lead to the formation of ion pairs at the surface that are designated as surface complexes. Different kinds of surface complexes can be discriminated.

Spectroscopic investigations of surfaces have given rise to the assumption that more than one single layer has to be assumed to account for the uptake of counterions. A typical approach used by many authors is the triple-layer model consisting of surface, inner and outer layers.

A further refinement of the triple-layer model is the approach developed by Horst. In this model individual sorption layers are credited to each kind of counterions. The respective theoretical approach allows the description of pure cation or anion exchange equilibria as well as of amphoteric equilibria encountered with activated alumina or activated carbon.

Theory

Amphoteric Reactions at a Charged Surface

Derivation of the mathematical relationships uses a generalized exchanger whose surface contains

S–OH groups as functional sites. In aqueous systems these surface groups can be protolysed in two different ways.

In acid media the surface may be protonated according to:

In order to maintain the condition of electroneutrality the charge on the surface has to be balanced by the negative charge of an anion, e.g.:

Therefore, in sufficiently acid media, a sorption of acids takes place similar to the uptake by weakly basic exchange resins.

In alkaline solutions the surface hydroxyl groups can dissociate and hand protons over to the liquid phase:

The negative surface charge has to be balanced by cations, e.g. by sodium ions:

Together the formal equation [3] and [4] represent a cation exchange on an arbitrary cation exchanger.

Each of the above models holds for the uptake of acids or the exchange of protons for other monovalent cations in arbitrary pure anion or cation exchange processes. If the state of equilibrium is considered for an amphoteric exchanger and a liquid phase containing different cations and anions, then the uptake of anions will decrease with increasing pH value until the sorption is completely suppressed. In the same direction the cation exchange of protons for cations increases. The pH regions of almost exclusive cation and anion sorption are separated by a maximum of noncharged surface groups. In this transition region sorption of both cations and anions occurs. At the point of zero charge, therefore, the surface is covered with equal amounts of equivalents of positively and negatively charged counterions.

Surface Model Assumptions

During the protonation, or dissociation, of the surface OH groups either a negative or a positive surface

potential is generated, depending on the pH and on the ionic strength of the liquid phase. Therefore, the respective counterions are subject to an attraction while the co-ions are rejected. Due to the sorption of counterions at functional groups, the surface potential is partly decreased. Unlike the description widely used in the literature, it is assumed that each kind of counterion is located at a characteristic distance from the surface. Thus, ordered double or 'Stern' layers are formed. Ion pairs between surface groups and counterions in the ordered layer are designated as surface complexes. Excess charges at the surface are balanced by counterions in the diffuse layer, which also contains co-ions. As a consequence, the surface potential continuously decreases normal to the surface to zero in the liquid phase. The equilibrium between solid and liquid phases is mainly dominated by protolytic reactions. In this way, the protons are the potential-determining species.

For a system with Cl^- and Na^+ ions the schematic arrangement of counterions and co-ions and the corresponding development of the potential are plotted in Figure 1. With respect to the radii of the hydrated species, the anion layers are assumed to be closer to the surface than those of the cations. (Cl^- and Na^+ ions are used as model counterions. Individual properties are not taken into account. Furthermore, the absolute values of the potential in the different layers are of no importance for the further mathematical derivations.)

General Sorption Equilibrium Relationships for an Amphoteric Surface

The derivation of equilibrium relationships makes use of the following assumptions:

1. The functional groups are uniformly distributed across a plane surface.

Figure 1 Schematic arrangement of ions at the amphoteric surface of activated alumina and the respective development of electrical potential.

- Activity coefficients in the exchanger phase are assumed to be 1.
- Any ion exchange develops as the replacement of one surface complex by a new one. As a consequence, an oxide valence is defined that is equal to the smallest common multiple of the valences of the counterions.

For the derivation of the equilibrium relationships a simple system with Cl^- and Na^+ ions is considered. The protolytic reactions at the surface are considered as local equilibria that can be described by the mass action law. The formation of the two surface complexes can be described by the respective formation constants, K (see Table 1 for explanation of symbols used).

Protonation

$$K_H^+ = \frac{c(\text{S-OH}_2^+)}{c(\text{H}^+)_s \cdot c(\text{S-OH})} \quad [6]$$

where c is the concentration of the species in parentheses in mol L^{-1} .

Dissociation/neutralization

$$K_H^- = \frac{c(\text{S-OH})}{c(\text{S-O}^-) \cdot c(\text{H}^+)_s} \quad [8]$$

The sorption of counterions leading to two further surface complexes is considered in an analogous way.

Sorption of anions

$$K_{\text{Cl}}^- = \frac{c(\text{S-OH}_2\text{Cl})}{c(\text{S-OH}_2^+) \cdot c(\text{Cl}^-)_s} \quad [10]$$

Sorption of cations

$$K_{\text{Na}}^+ = \frac{c(\text{S-ONa})}{c(\text{S-O}^-) \cdot c(\text{Na}^+)_s} \quad [12]$$

Symbols with subscript 's' designate concentrations in the respective Stern layer. These unknown quantities can be expressed in terms of the concentrations in the

Table 1

Symbol	Unit	Definition
A_0	$\text{m}^2 \text{g}^{-1}$	Specific surface area
$\alpha(i)$	mol L^{-1}	Concentration of species i
$\alpha(i)_s$	mol L^{-1}	Concentration of species i in the Stern layer
$\alpha(i)_x$	mol L^{-1}	Concentration of species i at position x in an electrical field
$C(i, j)$	F m^{-2}	Electric capacitance of capacitor formed by the layers of species i and j
$C(\text{S}, i)$	F m^{-2}	Electric capacitance of capacitor formed by the surface and the layer of species i
F	A s	Faraday constant
K_i^{\dagger}	—	Equilibrium constant of surface reaction
L	L	Volume of liquid phase
LS	—	left-hand side expression of eqns [38] and [39]
$m(\text{H}, j)$	—	Abbreviation, defined by eqn [22]
$q(i)$	mol g^{-1}	Oxide loading with species i
q_{max}	mol g^{-1}	Maximum exchanger loading
Q_i^{\dagger}	—	Generalized separation factor
R	$\text{J mol}^{-1} \text{K}^{-1}$	Gas constant
S	g	Mass of sorbent
S-	—	Abbreviation used to designate the surface
T	K	Temperature
V	—	Sign of charge
$\gamma(i)$	—	Dimensionless loading with species i
$\gamma(i, i)$	—	Probability of the presence of two adjacent ions, i at the surface
$z(i)$	—	Valence of species i
σ_i	A s m^{-2}	Surface charge density of layer with ions i
ψ_x	V	Electrical potential at position x

liquid phase by means of the Poisson–Boltzmann relationship:

$$c(i)_x = c(i) \times \exp \left\{ -\frac{z(i)F}{RT} \times \psi_x \right\} \quad [13]$$

Here $c(i)_x$ represents the concentration of species i at position x in an electric field, $z(i)$ is the valence of species i , F is the Faraday constant, ψ_x is the electrical potential at position x , R is the gas constant, and T is the temperature in Kelvin.

The uptake of anions develops as the simultaneous sorption of protons and chloride ions. Since we have a sequence of reactions, the equilibrium of this common sorption can be expressed by the product of the respective formation constants:

$$K_{\text{Cl}}^{\text{H}} = K_{\text{H}}^+ \times K_{\text{Cl}}^- \quad [14]$$

The uptake of cations, however, develops as the competitive sorption of protons and sodium ions. As a consequence, the equilibrium of the cation exchange is expressed by the ratio of the corresponding formation constants:

$$K_{\text{Na}}^{\text{H}} = \frac{K_{\text{H}}^{-}}{K_{\text{Na}}^{+}} \quad [15]$$

By means of eqns [6]–[15] one obtains:

$$K_{\text{Cl}}^{\text{H}} = \frac{c(\text{S-OH}_2\text{Cl})}{c(\text{S-OH}) \cdot c(\text{Cl}^{-}) \cdot c(\text{H}^{+})} \times \exp \left\{ + \frac{F}{RT} (\psi_{\text{S}} - \psi_{\text{Cl}}) \right\} \quad [16]$$

$$K_{\text{Na}}^{\text{H}} = \frac{c(\text{S-OH}) \cdot c(\text{Na}^{+})}{c(\text{S-ONa}) \cdot c(\text{H}^{+})} \times \exp \left\{ \frac{F}{RT} (\psi_{\text{S}} - \psi_{\text{Na}}) \right\} \quad [17]$$

Multiplying by the volume of the liquid phase and dividing by the mass of sorbent, the concentrations of surface complexes are converted to exchanger loadings $q(\text{OH})$, $q(\text{Cl}^{-})$, and $q(\text{Na}^{+})$ respectively; $q(\text{OH})$ denotes nonionized surface groups.

As a consequence, the first factor on the right-hand sides exclusively contains quantities that can be derived from experiments. Both expressions are designated as *generalized separation factors*, Q . After introducing dimensionless loadings with species i , $y(i) = q(i)/q_{\text{max}}$, where q_{max} is the maximum exchanger loading, the following expressions are obtained:

$$Q_{\text{Cl}}^{\text{H}} = \frac{q(\text{Cl})}{q(\text{OH}) \cdot c(\text{H}^{+}) \cdot c(\text{Cl}^{-})} = \frac{y(\text{Cl})}{y(\text{OH}) \cdot c(\text{H}^{+}) \cdot c(\text{Cl}^{-})} \quad [18]$$

$$Q_{\text{Na}}^{\text{H}} = \frac{q(\text{OH}) \cdot c(\text{Na}^{+})}{q(\text{Na}) \cdot c(\text{H}^{+})} = \frac{y(\text{OH}) \cdot c(\text{Na}^{+})}{y(\text{Na}) \cdot c(\text{H}^{+})} \quad [19]$$

Similar relationships can be derived for any monovalent counterion.

The difference of electrical potentials in the exponential terms of eqns [16] and [17] needs consideration about the surface charge densities in the series of electric capacitors formed by the surface, Stern and diffuse layers. As has been shown in earlier publications, the unknown differences in the electrical potential can be expressed in terms of the loading

of the surface with Cl^{-} and Na^{+} ions. After resolving the equations for the generalized separation factor one obtains:

$$\log Q_{\text{Cl}}^{\text{H}} = \log K_{\text{Cl}}^{\text{H}} + m(\text{H}, \text{Cl}) \times [-y(\text{Cl}) + y(\text{Na})] \quad [20]$$

$$\log Q_{\text{Na}}^{\text{H}} + m(\text{H}, \text{Cl}) \cdot y(\text{Cl}) = \log K_{\text{Na}}^{\text{H}} + m(\text{H}, \text{Na}) \cdot y(\text{Na}) \quad [21]$$

The terms $m(\text{H}, i)$ are given by the following equation:

$$m(\text{H}, i) = \frac{1}{12.303} \times \frac{q_{\text{max}} \cdot F^2}{A_0 \cdot C(\text{S}, i) \cdot RT} \quad [22]$$

where A_0 is the specific surface area and $C(\text{S}, i)$ denotes the capacitance of the capacitor formed by the surface and layer i . The derivation has been given in the literature.

For a system with an arbitrary number of monovalent counterions, the following relationship can be deduced from similar considerations:

$$\log Q_i^{\text{H}} = \log K_i^{\text{H}} + \sum_{j=2}^{i-1} \{m(\text{H}, j) \cdot V(j) \cdot y(j)\} + m(\text{H}, i) \sum_i^n \{V(i) \cdot y(i)\} \quad [23]$$

$$i = 2, 3 \dots, n \text{ index of counterions}$$

$$j = 2, 3 \dots, i - 1 \text{ running index}$$

Hydrogen ions are always taken as component '1'. The factors $V(j)$ and $V(i)$ are the signs of the charge of the ions having the values of -1 for anions and $+1$ for cations. The first summation comprises counterions from index '2' to ' $i-1$ ' (closer to the surface than species ' i '). The second summation considers the counterions with indices running from ' i ' to ' n '. For a system with n counterions there are $n-1$ equations [23]. By subsequent evaluation of data all constants $\log K_i^{\text{H}}$ and $m(\text{H}, i)$ can be derived from the multicomponent system.

During the exchange of one divalent counterion for two monovalent ions, one divalent ion replaces two adjacent monovalent species at the surface, where at least one divalent species of counterion is present, the sorbent has to be assumed to have divalent functional sites in the mathematical treatment (assumption 3). As a consequence, a surface complex consisting of two sites and two monovalent counterions is defined that is replaced by a surface complex which consists of two sites with one divalent counterion. For a system with H^{+} , Na^{+} , Cl^{-} and SO_4^{2-} the generalized

separation factors are then given by the following expressions:

$$Q_{\text{II}SO_4}^H = \frac{c\{(S-OH)_2 = SO_4\}}{c\{S-OH, S-OH\} \cdot c(H^+)^2 \cdot c(SO_4^{2-})} \quad [24]$$

$$Q_{\text{II}Cl}^H = \frac{c\{S-OH_2Cl, S-OH_2Cl\}}{c\{S-OH, S-OH\} \cdot c(H^+)^2 \cdot c(Cl)^2} \quad [25]$$

$$Q_{\text{II}Na}^H = \frac{c\{S-OH, S-OH\}}{c\{S-ONa, S-ONa\} \cdot c(H^+)^2} \quad [26]$$

Here the subscript II refers to calculation under the assumption of divalent functional sites.

The probability of two adjacent monovalent counterions i at the surface is given by:

$$y(i, i) = \left(\frac{y(i)}{\sum y(j)} \right)^2 \times \sum y(j) \quad [27]$$

where $\sum y(j)$ is the sum of dimensionless loadings of all monovalent counterions with valences $+1$ and -1 .

By this means the above separation factors can be expressed as:

$$Q_{\text{II}SO_4}^H = \frac{y(SO_4) \cdot \{y(H) + y(Cl) + y(Na)\}}{y(OH)^2 \cdot c(H^+)^2 \cdot c(SO_4^{2-})} \quad [28]$$

$$Q_{\text{II}Cl}^H = \frac{y(Cl)^2}{y(OH)^2 \cdot c(H^+)^2 \cdot c(Cl)^2} \equiv [Q_{\text{II}Cl}^H]^2 \quad [29]$$

$$Q_{\text{II}Na}^H = \frac{y(OH)^2 \cdot c(Na^+)^2}{y(Na)^2 \cdot c(H^+)^2} \equiv [Q_{\text{II}Na}^H]^2 \quad [30]$$

If divalent functional sites are assumed for systems with exclusively monovalent counterions, then the equilibrium parameters $\log K_{\text{II}}^H$ and $m_{\text{II}}(H, i)$ can be transformed to the parameters for monovalent functional sites according to:

$$\log K_{\text{II}}^H = \frac{\log K_{\text{II}}^H}{2} \quad [31]$$

$$m_{\text{II}}(H, i) = \frac{m_{\text{II}}(H, i)}{2} \quad [32]$$

The subscripts I and II refer to the assumption of either monovalent or divalent functional sites. If a system contains monovalent and divalent counterions the entire calculation has to assume divalent functional sites. Equilibrium parameters derived from

systems with only monovalent counterions have to be converted corresponding to eqns [31] and [32].

Relationships for Pure Cation or Anion Exchange on Weak Electrolyte Resins

In the case of weakly acidic exchange resins there is no exchange of anions. Therefore, the terms for anions in the general equation [24] vanish. For a simple system with H^+ and Na^+ ions, eqn [21] simplifies to:

$$\log Q_{Na}^H = \log K_{Na}^H + m(H, Na) \cdot y(Na) \quad [33]$$

In a similar way, there is no exchange of cations by weakly basic exchangers. For the uptake of hydrochloric acid eqn [20] yields:

$$\log Q_{Cl}^H = \log K_{Cl}^H - m(H, Cl) \cdot y(Cl) \quad [34]$$

The uptake of anions by protonated functional groups is equivalent to the exchange of anions for hydroxyl groups:

A similar theoretical development of the exchange of OH^- for Cl^- ions leads to the equilibrium relationship:

$$\log Q_{Cl}^{OH} = \log K_{Cl}^{OH} + m(OH, Cl) \cdot y(Cl) \quad [36]$$

Relationships for Strong Electrolyte Exchangers

Relationships for the description of equilibria with strongly acidic and strongly basic resins can also be derived from the basic equation [23]. The difference, however, is that hydrogen ions cannot be assumed to be adsorbed in the innermost layer. In the case of the cation exchangers this can be explained by the fact that the exchanger is completely dissociated, even in the H^+ form. Furthermore, hydrated protons have a rather large diameter and, therefore, cannot be assumed to be located close to the surface. Similar considerations hold for strongly basic anion exchangers and hydroxyl ions. For both cases, therefore, the sequence of layers starts with the kind of counterions which in each is located the closest to the surface.

Liquid Phase Equilibrium Relationships

The liquid phase equilibrium is calculated by means of:

- the dissociation of water;
- the condition of electroneutrality; and
- mass balances for each component.

Figure 2 Development of the generalized separation factor for the weakly acidic ion exchange resins (A) LEWATIT CNP 80 and (B) AMBERLITE IRC 50 (by courtesy of Marcel Dekker Inc.).

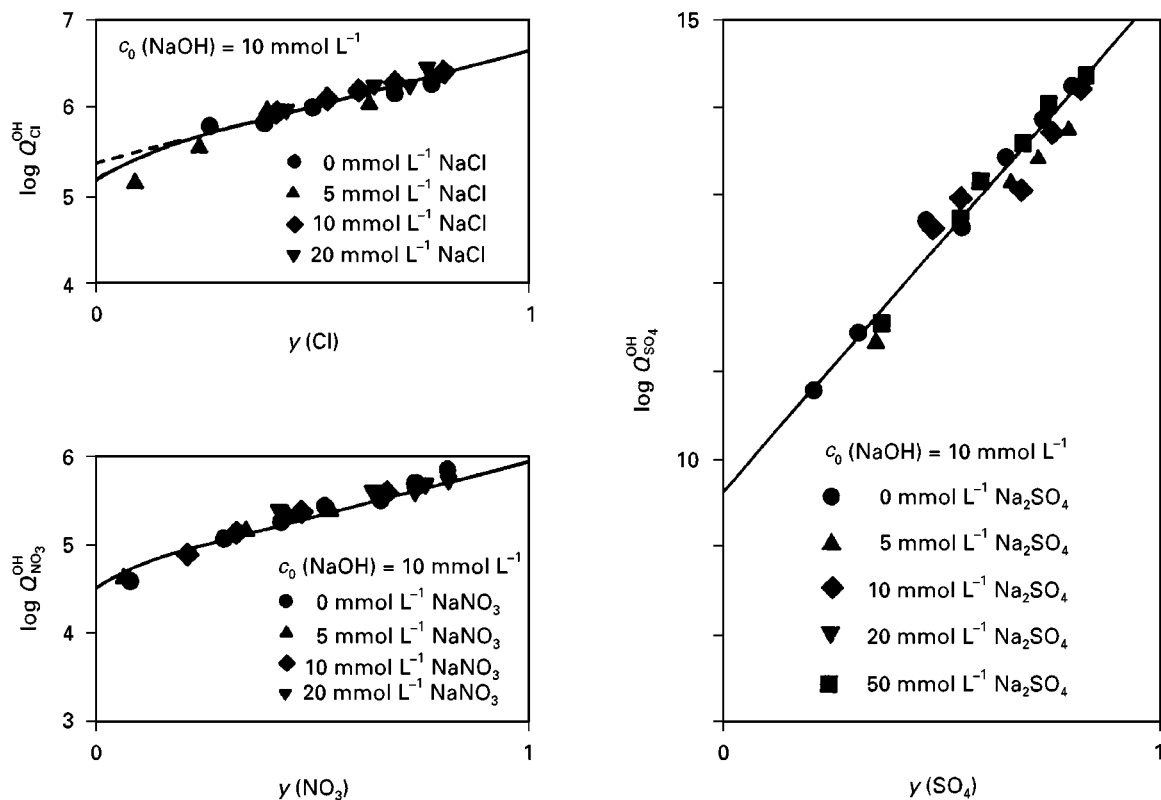

Figure 3 Development of the generalized separation factor for the weakly basic ion exchange resin AMBERLITE IRA 93 (by courtesy of Marcel Dekker Inc.).

Activity coefficients in the liquid phase can be calculated from the ionic strength using the extended Debye–Hückel relationship.

Experimental Evaluation of Equilibrium Data

General

Exchange equilibria have been determined for pure cation and anion exchangers as well as for amphoteric materials such as activated alumina and activated carbon. The pretreatment of these materials and the experimental conditions needed for obtaining proper equilibrium data have been described in detail in several publications. Cation concentrations can be measured by titration, photometric methods or by atomic absorption spectroscopy. Nitrate concentrations are measured photometrically, chloride and sulfate concentrations by ion chromatography.

In the case of pure anion or pure cation exchange, equilibria samples with increasing amounts of exchanger material are contacted with a fixed volume of the solution at constant temperature until equilibrium is obtained. Experiments with amphoteric equilibria are carried out at constant concentrations in the liquid phase and constant quantities of activated alumina or activated carbon in each of the samples. The volume/mass ratio is adjusted so that there is a substantial degree of sorption, as well as an equilibrium concentration that can be measured easily and with sufficient accuracy. Since the state of equilibrium is mainly dominated by the pH of the liquid phase, the pH value is varied in each series of samples. Details are described in the literature.

Evaluation of Data

For evaluation of equilibrium parameters the generalized separation factors have to be determined from equilibrium concentrations and resin loadings. These are then plotted against the respective dimensionless resin loading or the (algebraic) sum of resin loadings. In the case of binary systems with pure cation or anion exchange, the respective graphical representations directly yield the equilibrium parameters. The intersection of the linear relationship leads to $\log K$ and the slope of the straight line yields $m(i, j)$. Figures 2–5 show examples for different types of exchangers.

The results show that linear relationships are obtained in most cases. Systematic deviations are found for small loadings. This is attributed to the neglect of counterions in the diffuse layer. As has been demonstrated by Horst for simple systems, when this layer is considered, excellent agreement is obtained. For strongly acidic exchangers this region is compar-

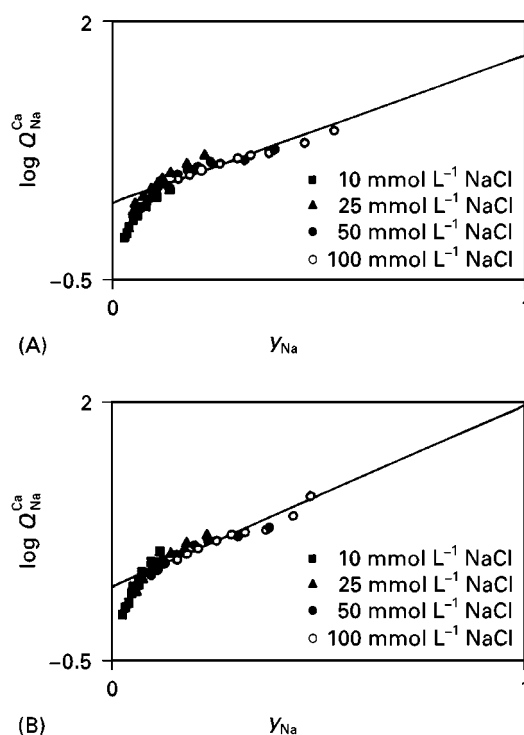

Figure 4 Development of the generalized separation factor for the exchange of calcium for sodium ions on two different strongly acidic resins. (A) Dowex HCRS; (B) LEWATIT S100.

atively larger than for other resin types. Evaluation of data for the exchange of sulfate for chloride on strongly basic exchangers shows that there are two different straight lines. There are clearly two different layers that are subsequently ‘filled’. Evaluation of data for a broad range of total concentrations up to 100 mmol L⁻¹ in the liquid phase reveals identical development of the linear relationships. For the entire range of ionic strength investigated the parameters can, therefore, be considered as ‘constant’ equilibrium constants.

Evaluation of amphoteric data requires a more sophisticated approach. The first step is the assumption of a certain sequence of layers. Evaluation of data starts with the evaluation of the equilibrium for the uptake of protons and ions in the first layer. The respective parameters are required for evaluation of the sorption of species in the next layer. Determination of the parameters for the third layer requires the sets of parameters for both the inner layers. This process has to be continued until all sets of binary parameters are derived. The sequence of a layers is assumed correctly if both the $\log K$ and $m(H, i)$ values show a steady increase with increasing distance. If this conditions is not fulfilled the calculation must be repeated with a modified sequence. Considering a system of layers H^+ , Cl^- , NO_3^- , Na^+ on activated alumina as an example, the equilibrium

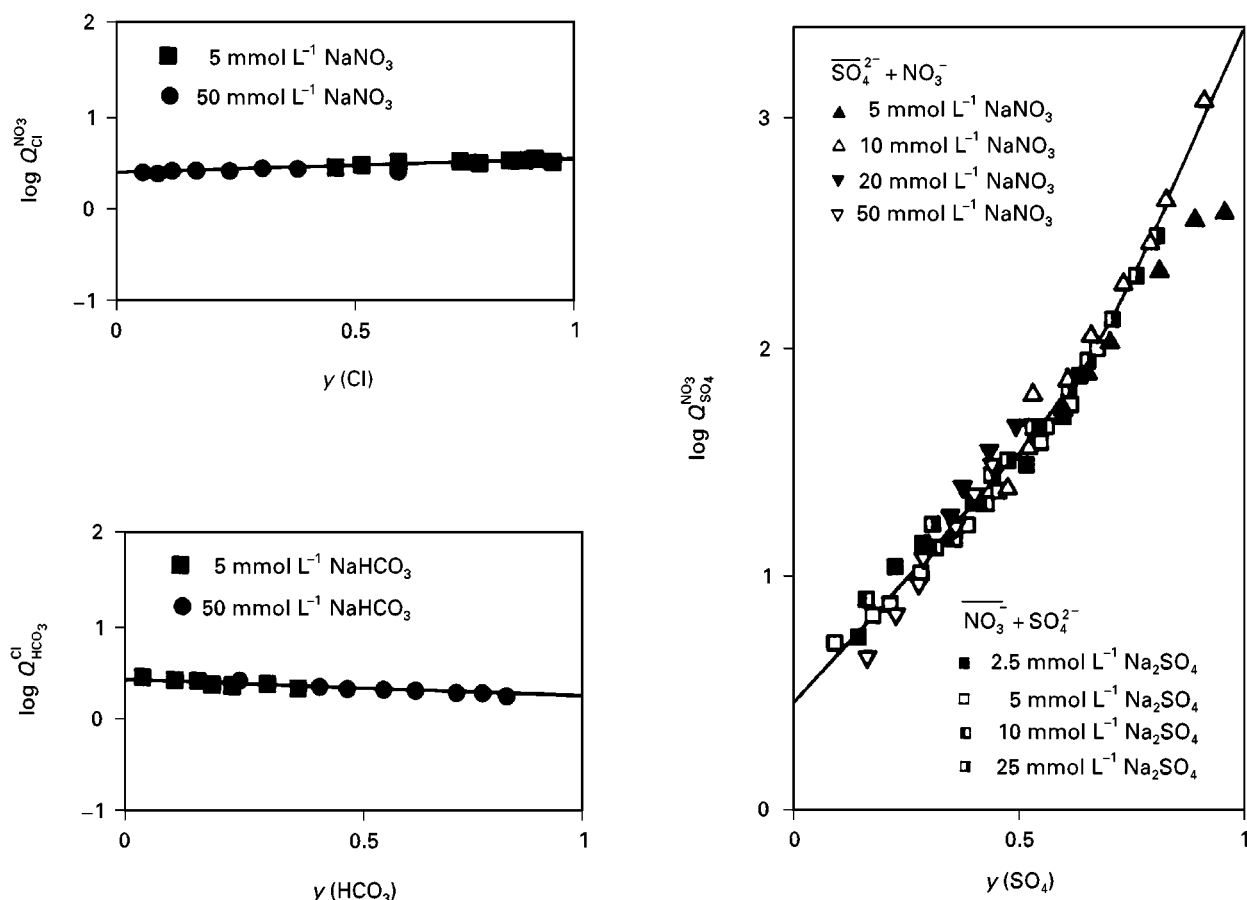

Figure 5 Development of the generalized separation factor for the strongly basic ion exchange resin AMBERLITE IRA 410 (Reprinted from Höll, Horst, Franzreb and Eberle (1993) by courtesy of Marcel Dekker Inc.).

parameters can be evaluated from the following relationships:

$$\log Q_{Cl}^H = \log K_{Cl}^H + m(H, Cl) \cdot \{ -y(Cl) \} \cdot \{ y(Na) - y(Cl) - y(NO_3) \} \quad [37]$$

Figure 6 Development of the generalized separation factor for the uptake of nitrate by activated alumina (COMPALOX AN/V800) from a multicomponent system (cation = Na^+ or K^+). The symbols represent different experiments.

$$\begin{aligned} & \log Q_{NO_3}^H - m(H, Cl) \cdot \{ -y(Cl) \} \\ &= \log K_{NO_3}^H + m(H, NO_3) \cdot \{ y(Na) - y(NO_3) \} \quad [38] \\ & \log Q_{Na}^H - m(H, Cl) \cdot \{ -y(Cl) \} - m(H, NO_3) \\ & \cdot \{ -y(NO_3) \} = \log K_{Na}^H + m(H, Na) \cdot y(Na) \quad [39] \end{aligned}$$

Figure 7 Development of the generalized separation factor for the sorption of sodium on COMPALOX AN/V800.

Figure 8 Development of the generalized separation factor for the sorption of carbonate species by activated carbon (NORIT ROW 0.8 Supra) from a multicomponent system.

Results of the evaluation of equilibrium data for the sorption of Cl^- , NO_3^- and Na^+ on activated alumina (COMPALOX AN/V800) are plotted in Figures 6 and 7. Although the results for the uptake of sodium ions are not satisfactory, the data demonstrate that linear relationships are obtained.

Prediction of Multicomponent Equilibria

General

Prediction of arbitrary exchange equilibria requires a set of conditions to be fulfilled:

- conservation of mass
- electroneutrality on the liquid phase
- electroneutrality on the resin phase
- adjustment of equilibrium for the exchange of ions
- dissociation equilibria in the liquid phase.

Figure 9 Development of the generalized separation factor for the sorption of chloride ions by activated carbon (NORIT ROW 0.8 Supra) from a multicomponent system. $LQ = \log Q(\text{H}, \text{Cl}) + m_{\text{II}}(\text{H}, \text{CO}_3)\gamma(\text{CO}_3) - m_{\text{II}}(\text{H}, \text{Ca})\gamma(\text{Ca}) - m_{\text{II}}(\text{H}, \text{Mg})\gamma(\text{Mg})$.

Figure 10 Comparison of experimental data and predicted equilibria for the ternary system $\text{H}^+/\text{Mg}^{2+}/\text{Ca}^{2+}$ on the weakly acidic resin LEWATIT OC 1046.

As can easily be shown, the number of equations is always greater than the number of unknown quantities. Therefore, some conditions are fulfilled automatically. The remaining set of coupled nonlinear equations must be solved by appropriate numerical methods.

Respective results for the uptake of inorganic ions by an activated carbon are plotted in Figures 8 and 9. With few exceptions, the equilibrium data satisfactorily fall on linear relationships as predicted by the theoretical approach.

Pure Cation or Anion Exchange

For prediction of multicomponent equilibria it is convenient if the binary parameters for the exchange of different counterions for the same reference ion have been deduced. For pure cation or anion exchange systems consideration of a three-component equilibrium with ions. A (reference ion), B and

Figure 11 Comparison of experimental data and predicted equilibria for the ternary system $\text{Cl}^-/\text{HCO}_3^-/\text{NO}_3^-$ on the strongly basic resin AMBERLITE IRA 410.

C leads to the relationships:

$$\log Q_B^A = \log K_B^A + m(A, B) \cdot [\gamma(B) + \gamma(C)] \quad [40]$$

$$\log Q_C^B = \log K_C^B + m(B, C) \cdot \gamma(C) \quad [41]$$

As has been demonstrated earlier, the binary parameters for the exchange of A versus B are the same as in the pure binary case. Also, the binary parameters for the exchange of A for C have been evaluated. In the above system, therefore, the parameters for the exchange of B for C are unknown. However, they can easily be calculated: the unknown parameter $\log K_C^B$ results from the definition:

$$\log K_C^B = \log K_C^A - \log K_B^A \quad [42]$$

For derivation of the unknown slope we make use of the fact that the sequence of layers can be considered as a series of layers of an electric capacitor. Since the

definition of $m(i, j)$ contains the electric capacitance, C , we can make use of the well-known relationship for capacitances in series:

$$\frac{1}{C(A, C)} = \frac{1}{C(A, B)} + \frac{1}{C(B, C)} \quad [43]$$

Thus, one obtains:

$$m(B, C) = m(A, C) - m(A, B) \quad [44]$$

Similar relationships are obtained for systems with more than three counterions. Examples of a comparison between experimental results and equilibria predicted from binary data are given in Figures 10–12.

For amphoteric sorbents the individual equilibrium parameters are already determined during evaluation of data. Therefore, no additional calculations are required. Figure 13 shows the comparison between experimentally determined oxide loadings and developments calculated by means of the set of equilibrium parameters determined previously. The data are plotted as relative loadings ($q(i)/q_{\max}$) as a function of pH. The system contained the four components H^+ , Cl^- , SO_4^{2-} and K^+ . Obviously, sulfate ions are preferred over chloride species. The constant sulfate loadings for pH values below 5 are due to the constant initial sulfate concentration in the system. Only minor loadings with monovalent cations are observed. There is excellent agreement with the predicted loadings.

Figure 14 shows the results from one experiment with activated carbon and protons, carbonate, sulphate, calcium, magnesium and potassium as counterions. The relative loadings with both carbonate and nitrate ions decrease with increasing pH of the solution, while the loadings of calcium and potassium slightly increase. Nevertheless their uptake

remains small, indicating that there is only a small capacity for the uptake of cations. Again, there is good agreement with the predicted developments.

Applications

The principal advantage of the surface complexation theory lies in the fact that it can be applied to any normal or reaction-coupled ion exchange process for which other theoretical descriptions of equilibria fail.

One field of application is the prediction of multi-species exchange kinetics. This has been demonstrated by Franzreb, who included the description into the solution of the Nernst-Planck equations for

several ternary and quaternary cases. The development of systems with strong and weak exchange resins and with normal and reaction-coupled multi-species processes could be predicted with excellent accuracy.

The surface complexation theory can also be easily applied to the simplified prediction of the performance of filters in which the filter is divided into a series of equilibrium stages. By means of the porosity of the filter section the quantities of resin material and liquid phase are known. Consequently, the exchange equilibrium in each stage can be calculated. The effluent composition of the filter is given by the equilibrium in the last stage. By this means and by an appropriate assumption of the number of

Theory of Ion Exchange

R. Harjula, University of Helsinki, Helsinki, Finland

Proper theoretical tools are necessary at all stages in the development of ion exchange applications. Firstly, in the laboratory, when a new application is being developed, theory is helpful in the design of new materials and necessary for the interpretation and quantification of research results. Secondly, theory is needed in the design of industrial and laboratory processes. When the process is being operated, theory is again useful to keep the process under optimal control.

Ion exchangers are used in very diverse applications in the laboratory and in industry. Considering this, and the fact that a very wide range of different substances can act as ion exchangers, it is not surprising to see in the literature that various sets of nomenclature, conventions and diverse theories exist, reflecting the special features of the applications or materials involved. For instance, one finds rather different definitions for several basic terms of ion exchange in the field of water purification compared to those used in ion exchange chromatography and even diversity in the terminology can be seen within the field of ion chromatography. It is inevitable that various theories must exist for the functioning of different types of ion exchangers, but the

discrepancies in the most basic definitions only lead to confusion and misconception that deter the utilization of the theory.

The theory of ion exchange is a vast subject. This article presents and discusses most of the essential theory and concepts in connection with the most common applications. There is emphasis on discussing details that are important in interpreting correctly research results and in predicting and optimizing ion exchanger performance. For simplicity, the basic equations are written for cation exchange but they are applicable to anion exchange as well, with minor modifications. Theories for the prediction of cation exchange selectivity are also discussed briefly.

Basic Concepts

Ion Exchange Equilibria

A binary ion exchange reaction between ion A (charge z_A) and ion B (charge z_B) may be written as:

where superscript bars refer to the ions in a solid ion exchanger. Various equilibrium quantities are used to measure and estimate the efficiency of the ion exchanger for a given separation task. The most common of these include the following.

Selectivity coefficient (selectivity quotient)

$$k_{A/B} = \frac{\bar{C}_A^{z_B} C_B^{z_A}}{\bar{C}_B^{z_A} C_A^{z_B}} \quad [2]$$

where \bar{C} s are the concentrations of the ions in the exchanger and C s those in solution. Various concentration units are commonly used (molar, molal, equivalent fraction, etc.). When $z_A \neq z_B$, the numerical value of $k_{A/B}$ depends on the choice of the concentration units. The selectivity coefficient ($k_{A/B}$) usually changes as a function of exchanger composition ($k_{A/B} = f(\bar{C}_A)$; see Figure 1) and also as a function of the total concentration (or ionic strength) of the external solution, especially in concentrated solutions.

Corrected selectivity coefficient By making the activity (nonideality) correction for the solution phase, the so-called corrected selectivity coefficient is obtained:

$$k'_{A/B} = \frac{\bar{C}_A^{z_B} a_B^{z_A}}{\bar{C}_B^{z_A} a_A^{z_B}} = \frac{\bar{C}_A^{z_B} C_B^{z_A} \gamma_B^{z_A}}{\bar{C}_B^{z_A} C_A^{z_B} \gamma_A^{z_B}} = k_{A/B} \frac{\gamma_B^{z_A}}{\gamma_A^{z_B}} \quad [3]$$

where a_A, a_B are the activities of ions A, B in the solution. This quantity is independent of the total concentration of the external solution by definition and thus reflects the pure exchanger-ion interactions contributing to the selectivity. In dilute solutions,

Figure 1 Selectivity coefficient $k_{Na/H}$ (see eqn [2]) for Na^+/H^+ exchange in sulfonated polystyrene/divinylbenzene (DVB) resins as a function of Na^+ equivalent fraction in resin at different degrees of cross-linking (nominal DVB content). Circles, DVB 5.5%; squares, DVB 15%; triangles, DVB 25%. (Data from Helfferich FG, 1995.)

$k'_{A/B} \approx k_{A/B}$. However, the corrected selectivity coefficient usually varies with the exchanger composition (\bar{C}_A).

Thermodynamic equilibrium constant The thermodynamic equilibrium constant $K_{A/B}$:

$$K_{A/B} = \frac{\bar{a}_A^{Z_B} \bar{a}_B^{Z_A}}{\bar{a}_B^{Z_A} \bar{a}_A^{Z_B}} = \frac{\bar{C}_A^{Z_B} \bar{C}_B^{Z_A}}{\bar{C}_B^{Z_A} \bar{C}_A^{Z_B}} \frac{\gamma_B^{Z_A}}{\gamma_A^{Z_B}} \frac{\gamma_B^{Z_A}}{\gamma_A^{Z_B}} = k'_{A/B} \frac{\gamma_B^{Z_A}}{\gamma_A^{Z_B}} \quad [4]$$

can be obtained by integrating the corrected selectivity coefficient as a function of exchanger composition. According to Argesinger *et al.* and Högfeldt *et al.*:

$$K_{A/B} = \int_0^1 \ln K_H d\bar{E}_A \quad [5]$$

where \bar{E}_A is the equivalent fraction of A in the exchanger ($\bar{E}_A = z_A \bar{C}_A / (z_A \bar{C}_A + z_B \bar{C}_B)$) and K_H is the corrected selectivity coefficient written with mole fractions (\bar{X}) as concentration units for the ions in the exchanger:

$$K_H = \frac{\bar{X}_A^{Z_B} \bar{C}_B^{Z_A}}{\bar{X}_B^{Z_A} \bar{C}_A^{Z_B}} \frac{\gamma_B^{Z_A}}{\gamma_A^{Z_B}} \quad [6]$$

Gaines and Thomas supplemented the abstract thermodynamic treatment to include the contributions of salt imbibition and water activity changes, which need to be considered when ions are exchanged in concentrated solutions.

Distribution coefficient (distribution constant, distribution ratio) Various distribution constants and coefficients are used to measure the ion exchange equilibria. In general, the distribution coefficient k_d of ion A is defined as a concentration ratio in the exchanger and solution:

$$k_d = \frac{\bar{C}_A}{C_A} \quad [7]$$

This quantity is only a constant under special conditions. In general, k_d depends on the ionic composition of the exchanger and the solution. For a binary exchange, one obtains from eqns [2] and [7] that:

$$k_d = k'_{A/B} \left(\frac{\bar{C}_B}{C_B} \right)^{\frac{Z_A}{Z_B}} \quad [8]$$

Under the special condition that A is present in the solution and in exchanger at much lower concentra-

tion than B ($C_A \ll C_B$, $\bar{C}_A \ll \bar{C}_B$), $k_{A/B}$ and \bar{C}_B are essentially constant ($\bar{C}_B \approx Q$, the ion exchange capacity) and:

$$\log k_d = \frac{1}{Z_B} \log (k_{A/B} Q^{Z_A}) - \frac{Z_A}{Z_B} \log C_B \quad [9]$$

Under these circumstances, k_d depends only on the concentration of ion B and, on a logarithmic scale, the slope of k_d equals $-z_A/z_B$, the ratio of cation charges.

Experimentally determined graphs of $\log k_d$ vs $\log C_B$ (eqn [9]) are frequently used in research to study sorption mechanisms, the charges of the exchanging species and in the estimation of exchanger performance, e.g. in water purification (estimation of processing capacity) and in ion chromatography (estimation of retention volume). Great care should be taken, however, in the interpretation of the data and in making sure that the assumptions leading to eqn [9] are valid. Because of the widespread use of distribution coefficients in ion exchange, it is useful to emphasize this point by taking a binary univalent exchange ($z_A = z_B = 1$) as an example here. For this equilibrium, eqn [9] can be further manipulated to give:

$$k_d = \frac{Q}{\frac{C_B}{k_{Cs/Na}} + C_A} \quad [10]$$

This equation now shows that, in fact, the condition for linear dependence of k_d on C_A ($\log k_d = \log (k_{A/B} Q) - \log C_B$) is that $C_A \ll C_B/k_{A/B}$. Thus, even if $C_A \ll C_B$, the dependence may not be linear if the selectivity coefficient is very large. This feature of k_d is shown as calculated examples in Figure 2. It can be seen that, if the selectivity coefficient is low, k_d falls linearly with the concentration of the macro-ion B, on a logarithmic scale with a slope of -1 , as eqn [9] implies. However, when the selectivity increases, the k_d starts to level off at lower concentrations of B and ultimately becomes independent of C_B when the selectivity is very high. In the studies of highly selective exchangers (zeolites and some other inorganic materials, chelating resins) such independence of k_d on the macro-ion concentration is often observed and every now and then the incorrect conclusion is made that the uptake of trace ions is not ion exchange but some sort of surface adsorption reaction. Figure 2 also shows an interesting feature of the link between k_d and selectivity: in dilute solutions the k_d s tend to a common value, which is determined by the ratio

Figure 2 Calculated values (eqn [10]) for the distribution coefficient k_d for trace ion A ($C_A = 10^{-6} \text{ mol L}^{-1}$) in binary univalent A^+/B^+ exchange as a function of macro-ion concentration C_B at different values of the selectivity coefficient $k_{A/B}$. Dotted line, $k_{A/B} = 5\,000\,000$; dashed line, $k_{A/B} = 50\,000$; continuous line, $k_{A/B} = 500$. Ion exchange capacity of the exchanger 2.0 mmol g^{-1} .

of Q/C_A . The value of selectivity thus becomes unimportant in dilute solutions.

In general, eqn [9] is valid for several parallel trace ion exchange reactions ($A, C, D \dots$) in the presence of one common macro-ion B , since the ions that are present at trace level will have a negligible effect on other trace ion equilibria.

Separation factor Separation factor is usually used in ion exchange chromatography to estimate the separability of two trace ions. Considering the separation of two trace ions A and C using macro ions B as an eluent, one obtains for the separation factor ($\alpha_{A/C}$):

$$\alpha_{A/C} = \frac{\bar{C}_A C_C}{C_A \bar{C}_C} = \frac{k_{d(A)}}{k_{d(C)}} = \left(\frac{k_{A/B}}{k_{C/B}} \right)^{\frac{1}{Z_B}} \left(\frac{\bar{C}_B}{C_B} \right)^{\frac{Z_A}{Z_C}} \\ = \text{Constant} / C_B^{\frac{Z_A}{Z_C}} \quad [11]$$

In the case that $z_A \neq z_C$, the separation factor increases as the concentration of B is decreased.

Ion exchange isotherm An ion exchange isotherm is a function that represents the ionic composition of the exchanger (\bar{E}_A) as a function of the ionic composition of the solution (E_A), or vice versa, at constant temperature (Figure 3). Traditionally, the selectivity of the exchanger is estimated from the isotherm. If the isotherm is concave towards the axis representing the ion concentration in the exchanger, the ion exchanger is considered to be selective for that ion (curves a and

b in Figure 3). If the isotherm lies on the diagonal of the presentation ($\bar{E}_A = E_A$), the exchanger has no preference for either ion A or B (curve c) and a bending of the isotherm towards the E_A -axis indicates that the exchanger is nonselective. The magnitude of the selectivity coefficient cannot be always deduced from the isotherm because when $z_A \neq z_B$, the shape of the isotherm depends strongly on the total ion concentration (C_T) in the solution. This behaviour arises from the difference between the cation charges, which can be clearly seen if the equation for the selectivity coefficient is expressed in terms of equivalent fractions and rearranged:

$$\frac{\bar{E}_A^{Z_B}}{\bar{E}_B^{Z_A}} = \frac{E_A^{Z_B}}{E_B^{Z_A}} k_{A/B} C_T^{(Z_B - Z_A)} \quad [12]$$

At a given point \bar{E}_A on the isotherm (the left-hand side of eqn [12] constant), the ratio E_A/E_B must decrease as C_T is decreased when $z_A > z_B$. Thus, the relative concentration of ion A must decrease with decreasing C_T . This feature, the increased preference of an ion exchanger for the ion having a higher charge with the dilution of the solution, is called electroselectivity. It should be also noted that the ion exchanger may prefer ion A strongly even though the value of the selectivity coefficient is equal to or less than unity (see calculated examples in Figure 3).

Ion Exchange Kinetics

The rate of ion exchange is governed by the various diffusion processes in the system. In general,

Figure 3 Calculated ion exchange isotherms for a hypothetical di-univalent (A^{2+}/B^{+}) exchange having a selectivity coefficient $k_{A/B} = 1$. The isotherms have been generated using constant total ion concentrations: 1, 0.01 mol L⁻¹; 2, 0.1 mol L⁻¹; 3, 1 mol L⁻¹; 4, 5 mol L⁻¹. The isotherms show increasing preference of the ion exchanger for ion A with increasing dilution of the solution (electroselectivity effect.)

diffusion can be described by Fick's first law. The flux of ion A (J_A) is given by:

$$J_A = -D \text{grad } C_A \quad [13]$$

where D is the diffusion coefficient. This equation describes purely statistical diffusion that is driven by the concentration gradient. In ion exchangers it is usually necessary to consider also the electric potential (ϕ) and then the flux of ion A (J_A) is given by the Nernst-Planck equation:

$$J_A = -D \left(\text{grad } C_A + z_A C_A \frac{F}{RT} \text{grad } \phi \right) \quad [14]$$

where F is the Faraday constant. Most commonly, the kinetics of ion exchange reactions are interpreted in the terms of external or internal diffusion. As the external solution is usually agitated, there is essentially no concentration gradient in the bulk of the external solution. Gradients arise, however, within a thin layer of solution adhering to the surface of the exchanger particle. Diffusion across this layer is called film diffusion. This concept, developed first by

Nernst, often satisfactorily describes the diffusion processes at solid-solution interfaces. The internal diffusion of the ions in the exchanger phase is called particle diffusion. Most often, the particle is considered homogeneous, so that the different diffusional processes within the particle (pore diffusion, matrix diffusion) are represented by a single particle diffusion coefficient. Either particle or film diffusion may be the rate-determining step for the exchange process or both may contribute to the rate in intermediate cases. In general, film diffusion may dominate at early stages of exchange (A low in exchanger, B low in solution) when the concentration gradient in the particle is large (fast rate in particle). However, as the exchange proceeds further, the concentration gradients in the particle decrease and particle diffusion may become the rate-determining step.

In the exchange process, ions A and B move in opposite directions. Therefore, generally, the so-called interdiffusion coefficient ($\bar{D}_{A/B}$) must be used in eqns [13] and [14]. For particle diffusion:

$$\bar{D}_{A/B} = \frac{\bar{D}_A \bar{D}_B (z_A^2 \bar{C}_A + z_B^2 \bar{C}_B)}{z_A^2 \bar{C}_A \bar{D}_A + z_B^2 \bar{C}_B \bar{D}_B} \quad [15]$$

Normally, the interdiffusion coefficient is not constant, but changes with the ionic composition (\bar{C}_A) of the exchanger. To calculate ion exchange rates in a given ion exchange system, the Nernst-Planck equations must be solved simultaneously for each diffusing species under boundary conditions specific to the system. In general, the resulting equations are nonlinear differential equations, which have analytical solutions only in some special cases. Such a case, for instance, is isotopic ion exchange, for which a so-called self-diffusion constant can be used. Assuming also that the solution has indefinite volume – the concentration of ion in the solution remains essentially constant – it is obtained for the half-time ($t_{1/2}$) of the exchange reaction. In the case of particle diffusion:

$$t_{1/2} = 0.030 \frac{r_0^2}{\bar{D}} \quad [16]$$

where r_0 is the radius of the exchanger particle and \bar{D} is the particle diffusion coefficient. For film diffusion:

$$t_{1/2} = 0.23 \frac{r_0 \delta Q}{DC} \quad [17]$$

where δ is the film thickness, Q the ion exchange capacity, D the film diffusion coefficient and C is the ion concentration. For particle diffusion (eqn [16]), the rate of exchange increases ($t_{1/2}$ decreases) as the particle radius decreases, being proportional to $1/r_0^2$. For film diffusion (eqn [17]), the rate increases less strongly as r_0 is decreased (the proportionality is to $1/r_0$). In film diffusion the exchange rate can also be increased by increasing the efficiency of agitation, which will decrease the film thickness. In real applications of ion exchange the exchange rates do not usually follow the simple relationships of eqns [16] and [17] and the equations are presented here just to give a simple view of the factors that can affect the ion exchange rates.

The values of film diffusion coefficients are of the same order of magnitude as the diffusion coefficients of ions in the external salt solution ($D \approx 10^{-5} \text{ cm}^2 \text{ s}^{-1}$). The values of particle diffusion coefficients depend strongly on the charge of the ion and on the structure and porosity of the exchanger matrix. In sulfonated polystyrene resins \bar{D} decreases with increasing degree of cross-linking, being in the range of 10^{-5} – $10^{-7} \text{ cm}^2 \text{ s}^{-1}$ for univalent cations. For multivalent cations, the values are much lower, falling in the range of 10^{-7} – $10^{-10} \text{ cm}^2 \text{ s}^{-1}$. In weakly acidic resins and in crystalline inorganic

ion exchangers, cation diffusion coefficients are typically 2–5 orders of magnitude lower.

Basic Ion Exchange Operations

Ion exchange reactions can be carried out as either batch or column operations. Column operation is far more common and efficient than batch operation. Batch operation is however used in research, because the experiment is simple to carry out and a large number of experiments can be carried out in parallel.

Batch Operation

In batch operation, a given amount (m) of ion exchanger is contacted with a given volume (V) of solution. The mixture is agitated until equilibrium has been attained. In typical binary batch process used for ion exchange studies (e.g. determination of $k_{A/B}$ as a function \bar{C}_A , Figure 1), the exchanger is initially in a homoionic form (e.g. the B form) and the solution initially contains only the ion A . Considering the simple uni-univalent exchange as an example, the ratio of ion concentrations at equilibrium is given by:

$$\frac{\bar{C}_A}{\bar{C}_B} = k_{A/B} \left(\frac{C_A}{C_B} \right) \quad [18]$$

In general, to achieve a high conversion to the A form in a single batch equilibration, the selectivity coefficient $k_{A/B}$ and the ratio C_A/B_B must be high. In practice, the degree of conversion to the A form is controlled by adjusting the initial concentration of A (C_{A0}) in the solution and the solution to solid ratio (V/m), often also called the batch factor (BF):

$$\bar{C}_A = (C_{A0} - C_A) \frac{V}{m} \quad [19]$$

At constant C_{A0} , the degree of conversion increases as V/m is increased (Figure 4). It is usually difficult to obtain a high conversion in a single batch equilibration, since the selectivity often decreases with increasing conversion and there is always ion B in the solution released from the exchanger. Removing B from the solution can enhance conversion. This can be achieved by equilibrating the ion exchanger successively with fresh portions of solution A .

Column Operation

There are several types of column operation, classified according to the technical design of the apparatus

Figure 4 Batch ion exchange: calculated degree of conversion from the B^+ form to the A^+ form as a function of solution volume to exchanger mass ratio (batch factor). Selectivity coefficient $k_{A/B} = 1$, ion exchange capacity 2 mmol g^{-1} . The solid line represent the conversion in single batch equilibration. The broken line represents successive batch equilibrations with a constant batch factor of 10 mL g^{-1} .

(e.g. fixed-bed or floating-bed operation) or according to the purpose of the application (e.g. column chromatography or column separation).

Column separation Column separation usually involves elimination of undesirable ions from water (deionization, softening, decontamination). Taking the binary exchange discussed earlier as an example, a solution containing harmful ions (A) is passed through the column that contains an exchanger in the B form. The A ions are then taken up by the exchanger and B ions are released into the solution. Because B ions are constantly removed from the system, the operation is much more efficient than batch exchange in removing A ions from the solution (see eqn [18]). The column effluent is first free of ion A , but when a given amount of solution has been passed through, A starts to emerge in the effluent and its concentration increases gradually to that in the influent solution (Figure 5). The graph of the concentration of A in effluent as a function of effluent volume is called the breakthrough curve.

The area above the breakthrough curve gives the total volume of solution that has been freed from ion A . Dividing this volume by bed mass or volume gives the total processing capacity, or theoretical capacity (Q_T), of the column (L kg^{-1} or L L^{-1}). In this simple example, $Q_T = Q/C_A$ (Q = ion exchange capacity in mmol L^{-1} or mmol mL^{-1}) since at equilibrium A ions have taken up all of the ion exchange capacity. In general, Q_T is equal to k_d , which can be easily calculated in binary systems from eqn [9] for trace ions

to be separated, provided that selectivity coefficients are known. However, because ion A is considered harmful, operation is not continued until total processing capacity has been used, but the feed is discontinued when the concentration of A in the effluent reaches a measurable or a regulated value. The capacity at this point is called the processing capacity, or breakthrough capacity (Q_B). The ratio Q_B/Q_T is called the column utilization factor, F_U . For efficient separation process F_U should be maximized.

Column chromatography In column chromatography ions are separated from each other for analysis or for chemical production purposes. Considering a simple example in which ions A and C are separated for analysis, a sample solution containing A and C is passed into the column containing an exchanger in the B form. The sample volume is so low that A and C take up only a very small fraction of the column capacity near the inlet. After sample injection, an eluent solution containing ion B is passed through the column. A and C in the exchanger are exchanged for B and begin to move through the column at different velocities. At a given volume, the less preferred ion A first emerges in the eluent as a concentration peak followed by ion C . The eluent volumes at which A and C emerge, i.e. the volumes at the peak maxima, are called the retention volumes (V_R) and they can be obtained from the relation:

$$V_R = k_d V_S + V_M \quad [20]$$

Figure 5 Examples of column breakthrough curves generated for different number of theoretical plates N (see eqns [22]–[27]). In this example, the capacity of the exchanger (Q) is 1 mmol mL^{-1} and the exchanger bed volume is 1 mL . The exchanger is initially in the B^+ form and the feed contains only ion A^+ at a concentration of $0.001 \text{ mmol mL}^{-1}$ (C_A). The total processing capacity Q_T is thus $Q/C_A = 1000 \text{ mL mL}^{-1}$ exchanger and the area above the breakthrough curves is 1000 mL for the 1 mL bed. The breakthrough capacity Q_B depends on N , which is affected by the operating conditions. Continuous line, $N = 30$; broken line, $N = 10$.

where V_S is the volume of ion exchanger bed and V_M is the free solution volume in the bed. In analytical separations A and C are present at trace levels, so k_d values are again easily calculated from eqn [9]. In analytical work, efficient operation requires that the concentration peaks of A and B are well separated (the peaks are sharp). The retention volumes V_R should not be too large, because this leads to a long analysis time and to broadening of the peaks.

Theory of Column Exchange

Most models for ion exchange column operation are based on the concept of effective plates or transfer units. Martin and Synge first used this concept for chromatography and the theory was refined by Glueckauf, who obtained for the material balance in the ion exchange column, under linear equilibrium (k_d constant):

$$\left(\frac{\partial C_i}{\partial z}\right)_v + q(k'_d + \beta) \left(\frac{\partial C_i}{\partial V}\right)_z - \frac{H}{2} \left(\frac{\partial^2 C_i}{\partial z^2}\right)_v = 0 \quad [21]$$

where z is the longitudinal coordinate in the column, q is the cross-sectional area of the bed, k'_d is the column distribution coefficient in which the exchanger phase concentration of species i is calculated per unit volume of the bed, i.e. k'_d is obtained from the k_d of eqn [7] as $k'_d = k_d (1 - \beta)$, where β is the bed void fraction. H is the effective height of the theoretical plate given by:

$$H = H_0 + H_p + H_F + H_L \quad [22]$$

H_0 , H_p , H_F and H_L are the contributions of particle size, particle diffusion, film diffusion and longitudinal diffusion to the effective height:

$$H_0 = 1.64 r_0 \quad [23]$$

$$H_p = \frac{k'_d}{(k'_d + \beta)^2} \frac{0.14 r_0^2 u}{\bar{D}} \quad [24]$$

$$H_F = \left(\frac{k'_d}{k'_d + \beta}\right)^2 \frac{0.266 r_0^2 u}{D(1 + 70r_0u)} \quad [25]$$

$$H_L = \frac{D\beta\sqrt{2}}{u} \quad [26]$$

where u is the linear flow rate. The number of theoretical plates (N) in the column is then obtained by dividing the column length L by H :

$$N = \frac{L}{H} \quad [27]$$

In general, the column performance improves as N is increased. In column separations the increase in N makes the breakthrough curve steeper (breakthrough capacity Q_T increases). In column chromatography, increase in N makes the elution peaks sharper and so increases the separation of two peaks. For a column with a constant length Z , N can be increased by decreasing the plate height H . The easiest way of doing this is to decrease the particle

radius (see eqns [23]–[25]), but there is a practical lower limit for r_0 , because the hydrodynamic pressure increases with decrease in r_0 . Another way to increase N is to decrease flow rate (eqns [24] and [25]), but a very low rate is not usually acceptable due to the effect of longitudinal diffusion (eqn [26]), which causes poor separation.

Equilibrium Theories

Much theoretical work has been carried out to explain the nonideality of the ion exchange systems, e.g. for the calculation of ion exchange equilibria and to understand the factors that give rise to ion exchange selectivity. For ions in solution, sufficient theories exist to calculate the nonideality (activities) in the liquid phase. For the ions in the exchanger phase, no generally valid theories exist. For the calculation of ion exchange equilibria, it is always possible to measure the nonideality of the exchanger phase, e.g. the corrected selectivity coefficient $k'_{A/B}$ as a function of exchanger ion composition at a given total solution concentration (C_T) and then use the measured function for the calculation of equilibria at other C_T values from equation:

$$k'_{A/B} \frac{\bar{E}_B^{Z_A}}{\bar{E}_A^{Z_B}} = \frac{E_B^{Z_A}}{E_A^{Z_B}} \frac{\gamma_B^{Z_A}}{\gamma_A^{Z_B}} C_T^{(Z_A - Z_B)} \quad [28]$$

In general, $k'_{A/B}$ and γ_A/γ_B are not known simultaneously, so iteration must be used to solve eqn [28]. The same approach can be extended to systems containing more than two counterions, e.g. for the ternary system the corrected selectivity coefficients $k'_{A/BC}$, $k'_{B/CA}$ and $k'_{C/AB}$ can be measured and used for the calculation of the equilibria. For instance, $k'_{A/BC}$ is defined as:

$$k'_{A/BC} = \frac{\bar{E}_A^{2Z_B Z_C} C_B^{Z_A Z_C} C_C^{Z_A Z_B} \gamma_B^{Z_A Z_C} \gamma_C^{Z_A Z_B}}{\bar{E}_B^{Z_A Z_C} \bar{E}_C^{Z_A Z_B} C_A^{2Z_B Z_C} \gamma_A^{2Z_B Z_C}} \quad [29]$$

for the exchange reaction:

$k'_{B/CA}$ and $k'_{C/AB}$ are defined accordingly. It is intrinsic to this method that it gives precise results provided that the selectivity coefficients are measured and described precisely within the exchanger composition range of interest. In practice this requires large number of measurements, which makes the method very laborious. Less effort is associated with ap-

proaches in which the solid-phase activity coefficients in multicomponent systems are estimated from the binary interaction parameters (Λ), e.g. from the Wilson equation it is obtained that:

$$\ln \bar{\gamma}_i = 1 - \ln \left(\sum_{j=1}^M \bar{X}_j \Lambda_{ij} \right) - \sum_{k=1}^M \left(\frac{\bar{X}_k \Lambda_{ki}}{\sum_{j=1}^M \bar{X}_j \Lambda_{kj}} \right) \quad [31]$$

Parameter Λ can be determined from the measurements of the corrected selectivity coefficients of the binary equilibria i/j , k/i and k/j by curve fitting. Activity coefficients obtained by eqn [31] are then used in the binary equations of thermodynamic equilibrium constant (eqn [4]) for the calculation of ion exchange equilibria. This method has given accurate results even in four-component systems (e.g. Na/K/Ca/Mg in a strong acid cation resin). Several other related approaches have been developed.

The theories above are based on the measurements of nonideality and make no assumptions about the interactions that give rise to the selectivity. Thus, they do not allow the calculation of $K_{A/B}$, $k'_{A/B}$ or $\bar{\gamma}_i$ from the fundamental data or explain the changes of $k'_{A/B}$ or $\bar{\gamma}_i$. The first theory to explain the nonideality of the exchanger phase was developed by Kielland (the graphical presentations of Figure 1 are often called Kielland plots), who considered van der Waals-type interactions and showed that for the solid-phase activity coefficients:

$$\bar{\gamma}_{AR} = c \bar{X}_{AR}^2 \quad [32]$$

$$\bar{\gamma}_{BR} = c \bar{X}_{BR}^2 \quad [33]$$

Here, AR and BR denote the salt forms of the exchanger, R being the common anion. This theory predicts that the function $k'_{A/B} = f(\bar{X}_A)$ is linear, which is in agreement with the observed behaviour in many cases. Quite often, the $k'_{A/B}$ functions are not linear, but slightly, or even strongly, curved (see Figure 1). Some of these nonlinear functions can be explained by assuming that the exchanger has several types of exchange sites, each subsite having a characteristic selectivity coefficient k'_i . The measured overall $k'_{A/B}$ decreases with \bar{X}_A as sites with higher selectivity are filled first. If these subsites behave ideally, sigmoidal curves are obtained for $k'_{A/B} = f(\bar{X}_A)$. By assuming nonideal behaviour for the subsites, the $k'_{A/B}$ functions exhibit a wide variety of different forms. This theory has been found to be consistent with the behaviour of several zeolite systems.

A related approach is to consider the different states that a given counterion may assume depending on the neighbouring counterions. In a polymer chain

(as in an organic ion exchange resin), considering the two nearest neighbours, each counterion can have three different energetic levels. As a consequence, in general $k'_{A/B} = f(\bar{X}_A)$ is a second-order polynomial function in \bar{X}_A , which is often the observed trend in organic resins (Figure 1). If two of the three energy levels are close to each other, the selectivity function is linear. Theories of this type are helpful in the calculation of ion exchange equilibria and in presenting the equilibria in a mathematical form, but they give no information about the magnitude of selectivity. In organic resins, various osmotic theories have been developed to estimate the relative magnitude of selectivity. The base in these theories is that:

$$K_{A/B} = \frac{\Pi}{RT} (z_B v_B - z_A v_A) \quad [34]$$

where Π is the osmotic pressure difference between the external solution and exchanger pore liquid and v_A and v_B are the partial molar volumes of A and B in the exchanger. The osmotic theory predicts the selectivity trend (I):

observed in strong-acid cation resins, i.e. ions with smaller hydrated radius (smaller partial molar volume) are preferred, because replacing larger ions with smaller ones will reduce the swelling pressure. The same selectivity trend can also be predicted from purely electrostatic calculations. The dielectric theory:

$$\ln K_{A/B} = \frac{-e^2}{8\pi kT} \left[\left(\frac{z_A}{r_A} - \frac{z_B}{r_B} \right) \left(\frac{1}{\varepsilon_Z} - \frac{1}{\varepsilon_S} \right) \right] \quad [35]$$

where ε_Z and ε_S are the macro-permittivities of the exchanger and solution phases, respectively, predicts that in uni-univalent exchange, the selectivity decreases as the framework charge density increases for selective exchange ($K_{A/B} > 1$). This trend is commonly observed for zeolite ion exchange.

The selectivity sequence I for alkali metal ions, shown above, is common in organic resins have a low degree of cross-linking and in zeolites with low framework charge density. Other selectivity sequences appear as the degree of cross-linking or framework charge density increases:

- II. $\text{Cs} > \text{K} > \text{Rb} > \text{Na} > \text{Li}$
- III. $\text{K} > \text{Cs} > \text{Rb} > \text{Na} > \text{Li}$
- IV. $\text{K} > \text{Cs} > \text{Na} > \text{Rb} > \text{Li}$
- V. $\text{K} > \text{Na} > \text{Cs} > \text{Rb} > \text{Li}$
- VI. $\text{K} > \text{Na} > \text{Rb} > \text{Cs} > \text{Li}$

- VII. $\text{Na} > \text{K} > \text{Rb} > \text{Cs} > \text{Li}$
- VIII. $\text{Na} > \text{K} > \text{Rb} > \text{Li} > \text{Cs}$
- IX. $\text{Na} > \text{K} > \text{Li} > \text{Rb} > \text{Cs}$
- X. $\text{Na} > \text{Li} > \text{K} > \text{Rb} > \text{Cs}$
- XI. $\text{Li} > \text{Na} > \text{K} > \text{Rb} > \text{Cs}$

Most of these sequences have been observed in ion exchangers and they can be predicted from Eisenman theory, originally developed for selective glass electrodes. The theory considers cation exchange site and cation water (hydration) interaction energies. The free energy of exchange is obtained from:

$$\Delta F_{AB}^0 = (\bar{F}_A^{\text{el}} - \bar{F}_B^{\text{el}}) - (\bar{F}_A^{\text{hyd}} - \bar{F}_B^{\text{hyd}}) \quad [36]$$

where F^{el} is the coulombic interaction energy between cation and the anionic exchange site and F^{hyd} is the hydration energy of the cation. The coulombic interaction energy for a univalent cation can be calculated for widely separated sites from:

$$\bar{F}_{\text{el}} = -332/(r_+ + r_-) \quad [37]$$

and for closely spaced sites:

$$\bar{F}_{\text{el}} = -1.56*332/(r_+ + r_-) \quad [38]$$

where r_+ is the cation radius and r_- is the radius of the anionic exchange site. The anionic field strength decreases as r_- increases. Selectivity pattern I is exhibited by exchangers having a low field strength and cations are exchanged in the hydrated state with a preference for a smaller hydrated radius. As the field strength is increased, the less hydrated cations become desolvated and the selectivity patterns start to change. At high field strength, pattern XI is exhibited and cations are exchanged as bare cations.

Conclusions

Rather simple theoretical concepts are available to describe ion exchange phenomena and applications in a qualitative manner. In some cases these concepts may give a good quantitative agreement, but generally more rigorous theories are required, considering the specific details of given systems. The application of even the simplest theories usually involves much experimental and computational effort when systems comprising more than two exchanging ions are involved.

MASS SPECTROMETRY

Spectrometry–Mass Spectrometry Ion Mobility

H. R. Bollan, DERA Bridgwater, Bridgwater, UK

Copyright © 2000 Academic Press

Introduction

The principle of mass spectrometry (MS) is the separation of ions in a vacuum, using an electrical or magnetic field or a combination of both. The ions may be formed through a variety of processes, but it is perhaps the fragmentation of the molecular ion that produces much of the analytical power of the technique. Mass-to-charge ratios are recorded and the structure of the parent ion may be determined from the ion molecular mass and the pattern of the fragment ions recorded. Experienced mass spectrometrists can recognize typical fragment ion patterns, however, although there are libraries available for the automated identification of mass spectra, careful judgement must be used in the final assignment of the compound's identity. The theory and uses of MS have been well documented as an analytical technique both as a stand-alone and a hyphenated technique, for example coupled with gas chromatography (GC-MS).

Less is known about the chemistry within ion mobility spectrometers, which are used in the field to monitor for contraband substances such as explosives, drugs, and on the battlefield to detect chemical warfare agents. Originally referred to as plasma chromatography, ion mobility spectrometry (IMS) is a technique concerned with the formation of ion-molecule clusters in air and their movement in an electric field, at or close to atmospheric pressure. The average ion velocity of an ion species in an electric field, v_d , is the product of that electric field, E , and

a constant of proportionality, K , i.e. $v_d = KE$. K is called the mobility of the ions, and is characteristic of a particular ion species in a specified drift gas. K may be calculated indirectly from drift time, t_d , from the equation $t_d = l_d/v_d$, where l_d is the drift length. The theory of ion mobility and reaction chemistry is covered in two monographs listed in the Further Reading section, and need not be reproduced here. Notably, the Mason–Schamp equation for mobility (an equation that attempts to reconcile fundamental properties of ions with their mobility) includes a term containing a collision integral, to which mobility is inversely proportional. The value of the collision integral is determined by the cross-section. Therefore, the mobility, and consequently the ion drift velocity, is dependent upon mass, size, shape, and polarizability. The mobilities observed for ions are weighted averages of the mobilities of all the cluster ions participating in a localized equilibrium between the ion swarm and the neutral molecules they encounter as they traverse the drift region. If the drift gas, electric field gradient, temperature, pressure, and therefore the molecular number density remain constant, mobility depends only on ion charge, reduced mass, and collision cross-section. The collision processes undergone by ions during their drift time are very complicated, and are much too complicated to go into here. However, it must be noted that these processes are affected by variations in temperature and pressure in the drift region. Ion cluster formation and fragmentation are also governed by temperature. Therefore, to simplify the situation, and to allow easy comparison between different systems, mobility of an ion is normalized for temperature and pressure, the corrected term being referred to as reduced mobility, K_0 (μ_0 in some texts).

The initial distribution of ions immediately following ionization is modified by various chemical

reactions, forming more stable ions. In clean air, these ions form what is called a reactant ion peak (RIP). Positive ion chemistry can involve proton transfer, nucleophilic attachment, hydride or hydroxide extraction, and oxidation; negative ion chemistry involves electron capture, charge transfer, dissociative capture, proton abstraction, and electrophilic attachment; both positive and negative chemistries can be subject to complex rearrangements.

When a sample atmosphere enters the ion mobility spectrometer, many competitive reactions occur and to a first approximation proton or electron affinities may define the reaction pathways. These competing species may be target or possible interference compounds. Ion mobility spectrometers respond to a broad range of compounds with various functional groups. Therefore, complicated spectra are common in ion-molecule systems based upon water chemistry, due to the relatively low proton affinity of the water molecule. Selectivity may be improved with the introduction of trace quantities of an appropriate dopant chemical into the detector carrier gas, thereby altering the degree of affinity required for reaction. This can have an effect on resolution, sensitivity, response and recovery times.

Whilst ion mobility spectrometers respond to many compounds, in the field the operator is only able to identify the compound being detected, by an ion mobility spectrometer, from its display. The efficacy of the instrument display depends upon calibration and software programming. However, as the observed peaks represent cluster ions participating in a localized equilibrium, even in the laboratory, with instrumentation capable of displaying the mobility spectra, the accurate identification of species may be difficult.

Although identification of unknowns by IMS alone is problematic, the coupling together of IMS and MS (IMS-MS) produces a powerful technique. The masses of ion-molecule clusters forming the RIP and product ion peaks are recorded either in positive or negative mode mass spectra, depending on the polarity of the ions being studied. When tuned ion analysis is performed on a specific mass in the mass spectrum, the mobility of the ion mass can be determined, i.e. its position in the mobility spectrum. With the technique enhanced, further by coupling IMS to tandem MS, the composition of ion-molecule clusters can be identified from the results of collision-induced dissociation (CID).

History

In the 1960s, Cohen (of the Franklin GNO Corporation) worked on the development of the ion mobility

spectrometer, resulting in a US patent in 1971. The instruments were developed to generate information concerning negative ions produced from specific compounds in air under atmospheric pressure conditions. This early instrumentation was to have wider application for the analysis of ultra-trace quantities of many organic molecules forming either positive or negative ions. Cohen went on to form the company PCP, and to produce commercially available IMS-MS instrumentation.

By the early 1970s, Karasek was already employing IMS as part of a hyphenated technique, using IMS-MS to determine the identity of species separated through a GC. Even without the GC in-line, it was becoming evident that IMS-MS was a powerful identification technique.

In the late 1970s and the 1980s, IMS research was directed from fundamental studies to application research, with a view to solving specific analytical problems relating to the rapid detection of volatile organic compounds in the field. Specifically, IMS was the subject of military research programmes, designed to enhance the real-time detection of chemical warfare agents. IMS-MS still played an important role in understanding the ion-molecule chemistry, which was necessary to progress the development and reliability of the field deployable IMS instrumentation. A study of the ion-molecule behaviour of selected agents and interference compounds has been made by IMS-MS. IMS-MS has also been used to support some of the IMS programmes that have been applied to more general, as well as specific, monitoring requirements. Industrial applications have been directed towards monitoring for toxic chemicals, and chemicals considered to be hazardous to man or the environment. These include acid and stack gases (e.g. hydrogen fluoride), aliphatic and aromatic amines, ketones, isocyanates, halogens, solvents, ethers, anaesthetics, fuels, nicotine, polychlorinated biphenyls, mixtures of organic compounds, organophosphorus compounds, certain hydrocarbons (e.g. benzene), perfluoroisobutene, and volatile organic compounds used in the semiconductor industry. With social pressures for a greener environment, further IMS techniques are being developed, for example, for the identification of polymers, using laser ablation-IMS, to assist with sorting plastics for recycling. The need to detect pollutants in liquid media is becoming more desirable, e.g. the detection of aniline in hexane, and of aqueous ammonia in rivers, wastewaters and drinking water treatment facilities. This problem requires a means of separating the analyte from the liquid medium, usually in the form of a selectively permeable membrane. IMS analysis proceeds once the analyte has been transferred from the liquid to the

vapour phase. IMS has also been investigated for the detection of bacteria in water and wastewater sources, using pyrolysis before introduction.

Detection of explosives is a specific and very important area of contraband detection at trace levels: RDX, TNT, PETN, NG, EGDN, HMX, EGDN, 2,4-DNT, ammonium nitrate, and tetryl detection by IMS have all been investigated. Detection of illicit drugs by IMS is another important area, which has benefited from confirmation of detected species by IMS-MS analysis. Due to legal requirements for forensic and law enforcement purposes, alleged criminals charged with the clandestine manufacture of illegal drugs in the USA must be charged with the manufacture of specific drugs in order for the case to go to court; a blanket charge of clandestine drug manufac-

ture is inadmissible. Drugs detected include heroin, cocaine, barbiturates, amphetamines, and LSD. Prescription drugs such as benzodiazepines are also detected by IMS. The pressure to be absolutely certain about the identity of target compounds emphasizes the advantages of powerful analytical techniques such as IMS-MS, which enhances the development and calibration of detection equipment.

A more specific application is of potential use to the forestry industry, which involves the identification of different timbers before processing. Fast thermolysis-IMS has proved successful for certain wood species. Wetwood, an abnormal condition of wood from both deciduous and coniferous trees caused by bacterial infection, was detected in Northern Red Oaks using this technique.

Although IMS-MS is necessarily a laboratory-based technique, it continues to play a very important part in the understanding of ion-molecule chemistry and the development of IMS equipment that, through user requirements, is becoming miniaturized. Hill continues to develop hyphenated IMS techniques, sometimes employing different ionization methods, including electrospray IMS-MS. The ion-molecule chemistry of different ionization techniques can be characterized readily by IMS-MS techniques. These fundamental studies have led the way for IMS-MS research into biomolecular sciences because, until the application of electrospray ionization, the biomolecules had been too large for successful ionization by more traditional methods employed for IMS. Clemmer and Jarrold were able to further the research by determining the conformation of biomolecules by IMS.

A chronology of the history of IMS-MS is given in Table 1.

An Ion Mobility Spectrometer–Mass Spectrometer

An ion mobility spectrometer consists of an ion-molecule reaction chamber, incorporating an ionization region, coupled to a drift region via a shutter grid. A schematic diagram is shown in Figure 1. The drift region contains a screen grid and an ion collector. A typical cell consists of metal guard rings, separated by insulators, connected to a resistance network with a high voltage attached to one end of the resistor chain, to produce a uniform electric field along the cell, usually of the order of a few hundred V cm^{-1} . Clean carrier gas is ionized by irradiation, usually with beta particles from a ^{63}Ni radioactive source, to form positive and negative reactant ions and consequently RIPs. The ion-molecule chemistry can be altered by the introduction of a dopant chemical at

Figure 1 Schematic of an ion mobility spectrometer.

a controlled rate. Samples introduced into the ion mobility spectrometer may react to form product ions, the equilibrium concentrations of which are governed by proton affinity or electron affinity. If introduced into an electric field they will migrate according to their polarity and that of the applied field as, between collisions, individual ions have a component of acceleration in the direction of the applied field. Ions pass from the reaction region to the drift region via a shutter grid, which is pulsed open to allow a finite number of ions to enter the drift region. Operation of the shutter grid starts the timing sequence, which measures drift time. A counter-flow of clean drift gas enters the drift region near the collector electrode, which is shielded by a screen grid in order to prevent induced charge, which would lead to a distorted current peak. By monitoring the collector electrode from the instant the voltage pulse is applied to the grid, a mobility spectrum (see **Figure 2**) is generated. Mobility spectra can be generated con-

tinuously by repetitive pulsing of the grid. Typically, 25 ms is sufficient time to allow all ions to drift from the grid to the collector electrode. The signal-to-noise ratio is relatively noisy because only small ion currents are involved. The signal-to-noise ratio may be improved by averaging the signal over several scans.

In a mass spectrometer, molecules are ionized by any one of a number of techniques. These ions are then analysed using either magnetic or electric fields or a combination of both and are separated according to their mass-to-charge ratio before being detected. In mass spectrometers using magnetic field separation, a repeller plate directs ions to a set of accelerator plates, used to produce a beam of rapidly moving ions, which are directed into a uniform beam by focussing slits. Neutral molecules are drawn off by vacuum pumps. In a quadrupole mass spectrometer, an oscillating electrostatic field is set up between four rods, two diagonally opposite rods having direct current voltage applied and the other two rods having radio frequency applied. Ions acquire an oscillation in the electrostatic field set up according to the ratio of the direct current to the radio frequency amplitude. Ions of the correct m/z value undergo a stable oscillation of constant amplitude and pass through the analyser to reach the detector. Other ions undergo unstable oscillation and the amplitude of the oscillation increases until the ions strike one of the rods.

Current IMS-MS Applications

APCI-MS enables ion chemistry at pressures used in typical IMS systems to be studied, but some issues remain regarding cluster formation in the interface region and this could influence the interfacing of IMS

Figure 2 An ion mobility spectrum.

Figure 3 An ion mobility spectrometer–mass spectrometer.

(which operates close to atmospheric pressure) to MS. However, Spangler has recently published details regarding a better understanding of the behaviour at the IMS-MS interface.

An ion mobility spectrometer may be coupled to a mass spectrometer (see **Figure 3**) with sample transfer via a pinhole, typically 50 μ to 100 μ in diameter. The mass spectrometer used in conjunction with an ion mobility spectrometer enables m/z identification of the reactant and product ions. The mass spectrometer is initially programmed to scan through the chosen mass range with the IMS shutter grids continuously open. (If the ion mobility spectrometer is used in the normal pulsed mode it may take a very long time to obtain a mass spectrum, which may then not be representative.) Thus, it is possible to record ions created in an ion mobility spectrometer, and a mass spectrum of IMS sample ions is shown in **Figure 4**.

The mass spectrometer is then programmed to detect ions of one chosen mass. In this 'tuned'

ion mode (with the IMS shutter grids operating normally), a drift spectrum of the selected ion species is generated (see **Figure 5**). Thus, it is possible to associate a particular ion mass with a particular ion mobility peak. Hence, IMS-tuned MS enables the reduced mobility for ions to be determined, but the signals are weak and a significant amount of data averaging is required. Because the signals are very low, mass spectrometers used in conjunction with ion mobility spectrometers are set to pulse counting mode. Sometimes the average of thousands of spectra is necessary to produce a mobility peak. Using IMS-quadrupole MS to determine the reduced mobilities of all the ion-molecule clusters in a mobility spectrum could take from several hours to days. IMS-TOF is much faster, because it is able to scan at 50 to 60 Hz about 1000 scans per mobility spectrum. Ewing and Stone have an IMS-tuned MS for investigating the kinetic thermodynamic relationship for the ion reactions.

Figure 4 A mass spectrum of IMS sample ions.

Figure 5 A drift spectrum of a selected ion species.

Figure 6 A mass spectrum of CID product ions.

IMS-MS-MS studies can be performed when IMS is coupled to a triple quadrupole mass spectrometer. An ion selected by the first quadrupole can be injected into a collision gas, for example argon, in a second quadrupole at 2×10^{-5} Torr (subjecting the cluster ions to CID), and then the product ions can be analysed in the third quadrupole. Figure 6 shows a mass spectrum of CID product ions. Consequently, MS-MS analysis is used extensively in assigning ion identities. IMS coupled to triple quadrupole MS enables the composite identification of the ion-molecules found in a drift tube. However, the number of ions reaching the detector in IMS-MS-MS is extremely low and a large amount of averaging is required to determine structures.

MEMBRANE SEPARATIONS

Bipolar Membranes and Membrane Processes

H. Strathmann, University of Twente, The Netherlands

Copyright © 2000 Academic Press

Bipolar membranes are gaining increasing attention as an efficient tool for the production of acids and bases from the corresponding salts by electroolytic water dissociation. The process is economically very attractive and has a multitude of interesting potential applications. The large scale utilization of bipolar membranes, however, is still limited today by unsatisfactory membrane properties and by a lack of application know-how. A bipolar membrane should have adequate water dissociation capability, low electrical resistance, high permselectivity and a long useful life under operat-

ing conditions, which means that it must be stable in highly concentrated acid or alkaline solutions. The monopolar anion and cation exchange membranes which are also needed in the process should have good proton and hydroxide ion-blocking capability in addition to stability in strong bases and acids.

Although today's membranes do not meet all of these required properties, they are used successfully in a number of relevant applications.

The Principle of Electrolytic Water Dissociation

The process of electrolytic water dissociation using a bipolar membrane is illustrated in **Figure 1**, which shows a bipolar membrane consisting of cation and anion exchange layers arranged in parallel between two electrodes. If an electrical potential difference is established between the electrodes, charged species are removed from the interphase between the

Figure 1 Schematic diagram illustrating the principle of electrolytic water dissociation in bipolar membranes.

two ion exchange layers. When all salt ions are removed from the interphase region, further transport of electrical charges can only be accomplished by protons and hydroxide ions, which are available in a concentration of *ca.* $1 \times 10^{-7} \text{ mol L}^{-1}$. Bipolar membranes resemble a laminate of a cation and an anion exchange layer with a very thin (4–5 nm) transition region in which the water dissociation occurs according to the water dissociation equilibrium given by:

The reversible energy required for the production of acids and bases in a bipolar membrane at constant temperature and pressure can be calculated by the Nernst equation for a concentration chain of solutions with different H^+ ion activities, i.e. pH values:

$$\Delta G = F \cdot \Delta U = 2.3 RT \Delta \text{pH} \quad [2]$$

Here ΔG is the reversible Gibb's free energy, ΔU the electrical potential difference between the two solutions, R is the gas constant, T is the absolute temperature, F is the Faraday constant, and ΔpH is the difference between the pH values of the two solutions separated by the bipolar membrane. For 1 mol L^{-1} acid and base solutions in the two phases separated by the membrane, ΔU is 0.8 V and ΔG is $0.02 \text{ kWh mol}^{-1}$ at 25°C .

The potential drop across the bipolar membrane measured in a water dissociation experiment is always higher than the calculated theoretical value because of irreversible effects due to the electrical resistance of the membrane and the solutions.

To utilize bipolar membranes for the production of acids and bases from the corresponding salt solution they must be combined with monopolar ion exchange membranes, as illustrated in **Figure 2**. This schematic drawing shows bipolar and cation and anion

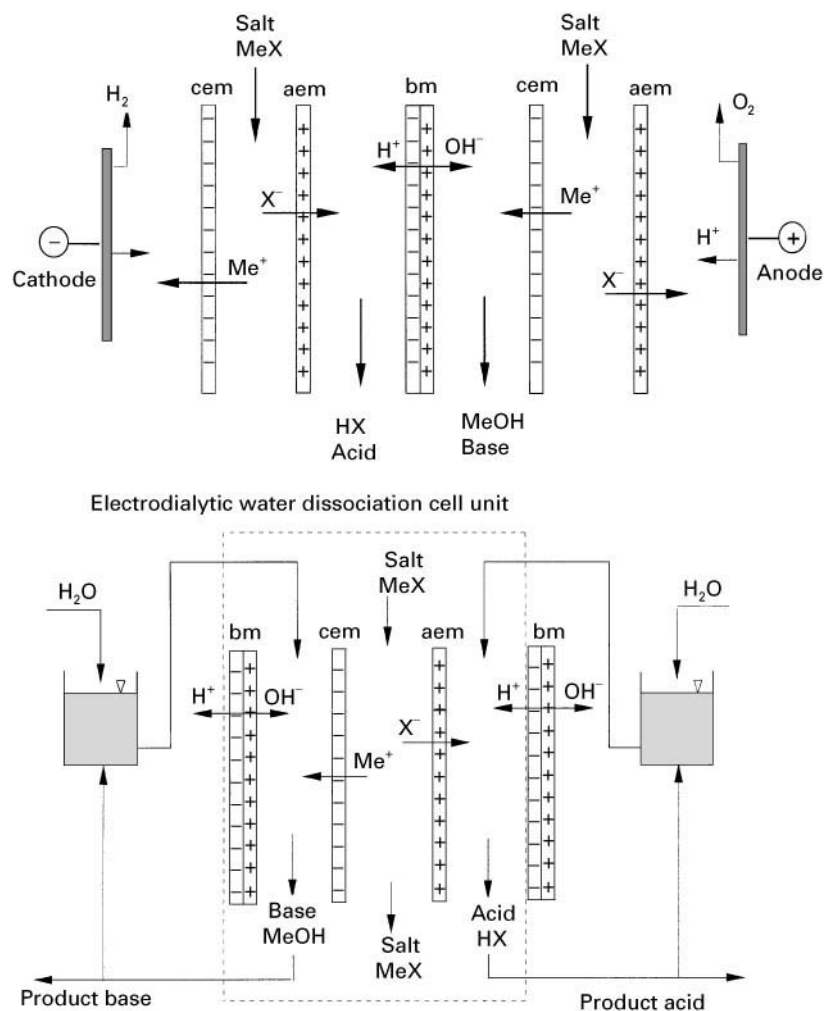

Figure 2 Schematic drawing illustrating the principle of electrodiolytic production of acids and bases from the corresponding salts with bipolar membranes.

exchange membranes arranged in parallel between two electrodes to form individual compartments. The electro dialysis cell arrangement consists of three individual compartments and three membranes, i.e. the bipolar and the cation and anion exchange membrane. As in conventional electro dialysis, a large number of the three-compartment units can be stacked between electrodes. When a salt solution is introduced in the middle compartment and an electrical potential difference between the electrodes is established, the cations in the salt solution migrate towards the cathode. They permeate the cation exchange membrane and form a base with the hydroxide ions generated in the bipolar membrane. On the other side of the bipolar membrane protons, which are generated simultaneously with the hydroxide ions, form an acid with anions migrating from the salt solution through the anion exchange membrane towards the anode. The net result of the process is the production of an acid and a base from the corresponding salt solution.

The Mechanism of Water Dissociation in Bipolar Membranes

The water dissociation rate in the bipolar membrane determines the overall efficiency of the process. It can easily be shown, however, that the dissociation rate constant of pure water is much too low to explain the experimentally determined high acid and base generation rate in bipolar membranes.

As indicated earlier, a bipolar membrane consists of a laminate of cation and anion exchange layers. The specific resistance σ of a strong acid or base ion exchange layer is in the order of 50–100 Ω cm. Assuming a thickness of 100 μ m each for the cation and anion exchange layers, the total area resistance r of the ion exchange layers of the bipolar membrane is in the order of 1–2 Ω cm².

The electrical resistance of the interphase layer of a bipolar membrane which is assumed to consist of deionized water can be calculated by:

$$r_{\text{in}} = \frac{\lambda}{\kappa} \quad [3]$$

where r_{in} is the area resistance, λ the thickness, and κ is the specific conductivity of the interphase layer. If the interphase layer contains only pure water, its specific resistance is approximately $18 \times 10^6 \Omega$ cm. Thus, the area resistance of a 1 nm thick interphase is approximately 1.8 Ω cm². The above argument however is only correct if the ion concentration in the interphase is constant and all ions which are removed

by the electric current across the bipolar membrane are replenished by the water dissociation. This means that the ion fluxes from the bipolar membrane into the outer phases cannot exceed the rate of their generation in the interphase. Thus, the maximum flux of H^+ and OH^- ions of the bipolar membrane is given by:

$$J_{\text{H}^+} = J_{\text{OH}^-} = k_d C_{\text{H}_2\text{O}} \lambda \quad [4]$$

where J is the maximum ion flux from the bipolar membrane into the outer phases, k_d is the water dissociation rate constant, $C_{\text{H}_2\text{O}}$ is the concentration of water in the interphase and λ is the thickness of the interphases. The subscripts H^+ , OH^- and H_2O refer to H^+ , OH^- ions and water, respectively.

The water dissociation rate constant k_d for pure water at 25°C is given in the literature as $2.5 \times 10^{-5} \text{ s}^{-1}$.

According to eqn [4], the maximum fluxes J_{H^+} and J_{OH^-} from a bipolar membrane that has a 1 nm thick interphase of pure water would be $1.4 \times 10^{-13} \text{ mol cm}^{-2} \text{ s}^{-1}$.

The electrical current I through the bipolar membrane is proportional to the sum of all ion fluxes and is given by:

$$I = F(J_{\text{H}^+} + J_{\text{OH}^-}) \quad [5]$$

Thus, the maximum current density through a bipolar membrane is, according to eqns [4] and [5], approximately $1.4 \times 10^{-8} \text{ A cm}^{-2}$. A current density exceeding this value would lead to a depletion of ions in the interphase and thus to a drastic increase in its electrical resistance. In practice, however, bipolar membranes can be operated at current densities in excess of 0.1 A cm^{-2} , as demonstrated in Figure 3A, which shows the current through a bipolar membrane as a function of the applied voltage. When an increasing voltage difference across a bipolar membrane is established, the current hardly increases until the voltage drop reaches a value of about 0.8 V, corresponding to the concentration potential calculated by eqn [2] for a pH value difference between the two solutions outside the bipolar membrane of about 14. A further small increase in the voltage then leads to a drastic increase in the current density to values in excess of 0.2 A cm^{-2} . Thus, the current–voltage curves determined with bipolar membranes show two plateau values that indicate a limitation in the current with increasing voltage drop across the membrane, as depicted in Figure 3B. The first plateau value indicates a limitation of the current density due to a limitation of ions in the interphase. However, at 0.8 V accelerated water dissociation begins and the current

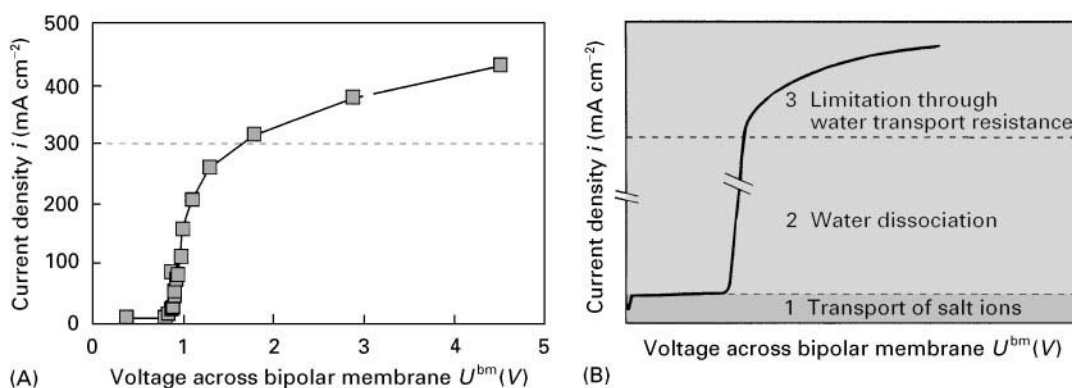

Figure 3 Schematic diagram of the current density as a function of the applied voltage (A) determined with a typical commercially available bipolar membrane and (B) three distinct areas of operation with bipolar membranes.

is no longer limited by a lack of ions until the second plateau value is reached at *ca.* 0.2 A cm^{-2} . Water dissociation is then limited by the supply of water to the interphase.

Thus, there are three distinct regions in the operation of a bipolar membrane. In the first region the current is very low and mainly transported by salt ions. In the second region, high water dissociation occurs and the current is transported by protons and hydroxide ions generated in the interphase. In the third region the production rate of protons and hydroxide ions is limited by the water transport rate into the interphase. Operation of bipolar membranes at current densities that exceed the second plateau value leads to destruction of the membrane.

The experimentally determined current densities indicate that the simple model of a bipolar membrane depicted in Figure 1 is incorrect. Either the water dissociation rate is faster by several orders of magnitude in the bipolar membrane than in free solution or the interphase is much thicker. A thick interphase, however, would lead to a high area resistance of the interphase, which is not the case. From scanning electron microscope photographs and calculations based on the Poisson and Boltzmann relation for the space charge at an interphase between differently charged ion exchange membranes, it can be concluded that the thickness of the interphase is less than 5 nm. This means that, in bipolar membranes the water dissociation is at least 10^6 times faster than in free solution.

Various mechanisms have been suggested to explain the accelerated water dissociation in bipolar membranes. One possible explanation, suggested by Wien, is that at high electric field densities the ion mobility as well as the degree of dissociation of weakly dissociated electrolytes increases with increasing field density. The increase in the dissociation constant of weak electrolytes by the electric field effect

can be expressed by an increase in the water dissociation rate constant, assuming that the recombination rate of H^+ and OH^- ions is unaffected.

Other theoretical considerations and experimental evidence support a hypothesis that the accelerated water dissociation is caused by a reversible proton transfer reaction between charged groups and water. This means that, in the presence of certain ionic groups, the water dissociation rate constant may be several orders of magnitude higher than in pure water. In the case of the bipolar membrane the anion exchange groups of the membrane polymer adjacent to the interphase layer are assumed to react with the water molecules at the membrane surface as follows:

where B is a neutral base, e.g. a tertiary ammonium group.

Both models can explain the acceleration of the water dissociation in the interphases between the anion and cation exchange layer of the bipolar membrane and serve as theoretical basis for the development of bipolar membranes.

The Preparation and Performance of Bipolar Membranes

The properties required of bipolar membranes to be useful in practical applications are low electrical resistance at high current density, high water dissociation rates, low co-ion transport rate, high ion selectivities, good thermal and, most importantly, good chemical stability since the cation-selective layer of the bipolar membrane is in direct contact with an

acid and the anion exchange layer with an alkaline solution.

Low electrical resistance of the cation and anion exchange layer of the bipolar membrane can be obtained by using a strong acid, such as sulfonic acid groups, and a strong base, such as quaternary ammonium groups as fixed charges in high concentrations in the polymer matrix. To minimize the resistance of the interphase between the cation- and the anion-selective layers the thickness of this interphase must be as thin as possible, as indicated earlier. There are various ways to prepare bipolar membranes with satisfactory properties. Most commonly, membranes are prepared as laminates with some kind of interphase which forms a transition region where the actual water dissociation takes place. In some membranes heavy metal hydroxides are deposited in the interphase to catalyse the water dissociation. However, tertiary ammonium fixed-charge groups at the surface of the anion exchange membrane seem to have the same effect.

A bipolar membrane with satisfactory properties can be prepared, e.g. as a laminate of highly permselective anion and cation exchange layers which have good alkaline and acid stability. An anion-selective layer with the required properties can be obtained by reacting chloromethylated polysulfone dissolved in *n*-methyl pyrrolidone with the monoquaternary salt of 4,4'-diazabicyclo-[2.2.2]-octane. The cation-selective layer can be prepared by introducing sulfonic acid groups as fixed charges into a polyether-ether-ketone matrix using chlorosulfonic acid. The co-ion transport and the swelling behaviour can be controlled in both layers by partial cross-linking. The properties of ion exchange membranes prepared following the above procedures are listed in Table 1.

The Performance of Bipolar Membranes

Bipolar membranes are usually characterized in terms of their water dissociation capability, their resistance

and their long-term stability. The water dissociation rate and electrical resistance of a membrane prepared by the procedure described above is shown in Figure 3A. Here the current density is shown as a function of the potential drop across the membrane. The test solutions in both compartments adjacent to the bipolar membrane are 1 molar Na₂SO₄. The results indicate that the current density is extremely low at potential differences of less than *ca.* 0.8 V. Then the current density increases up to 0.250 A cm⁻² with very little increase in voltage drop. When this value is exceeded, the resistance of the membrane increases drastically, due to limitations in the water transport into the interphase region.

Problems in Practical Applications of Bipolar Membranes

Electrodialytic dissociation of water with bipolar membranes is economically very attractive for creating acids and bases. There are, however, several severe problems in practical applications, such as the contamination of the products by salts and low current efficiency at high acid and base concentrations.

Salt contamination of the products is related to the properties of the bipolar membrane. The poor current efficiency is the consequence of the proton and hydroxide ion transport in monopolar membranes, as indicated in Figure 4, which illustrates the conversion of Na₂SO₄ into H₂SO₄ and NaOH by electrodialytic water dissociation. Figure 4(A) shows the ion transport in the bipolar membrane. What is desired is a flux of H⁺ and OH⁻ ions from the interphase of the bipolar membrane as the result of the water dissociation. However, in addition there is a flux of Na⁺ and SO₄²⁻ ions through the bipolar membrane due to incomplete permselectivity of the anion and cation exchange layers. This leads to a contamination of the base by SO₄²⁻ ions and the acid by Na⁺ ions. Since the permeability of the ion exchange layers to SO₄²⁻ and Na⁺ increases with increasing acid and base concentration, the contamination is also increasing with increasing concentration, as shown in Figure 4B. This figure shows the salt contamination in sulfuric acid and sodium hydroxide produced by water dissociation in bipolar membranes from a 1 mol L⁻¹ Na₂SO₄ solution as a function of the concentration of the acid and base produced.

The current efficiency in water dissociation with bipolar membranes is mainly affected by the properties of the anion exchange membrane which has very poor retention of the protons, as illustrated in Figure 4C. The transport mechanism of protons is based on a tunnelling mechanism, with the consequence that protons can permeate the anion

Table 1 Electrochemical properties of the cation- and anion-selective layers of a bipolar membrane prepared by the technique described above

	Anion exchange layer	Cation exchange layer
Ion exchange capacity (mmol g ⁻¹)	1.2	1.0
Membrane thickness (μm)	60	60
Area resistance (Ω cm ²)	1.05	1.31
Permselectivity (%)	97.5	98.5
Swelling (%)	8	12.5

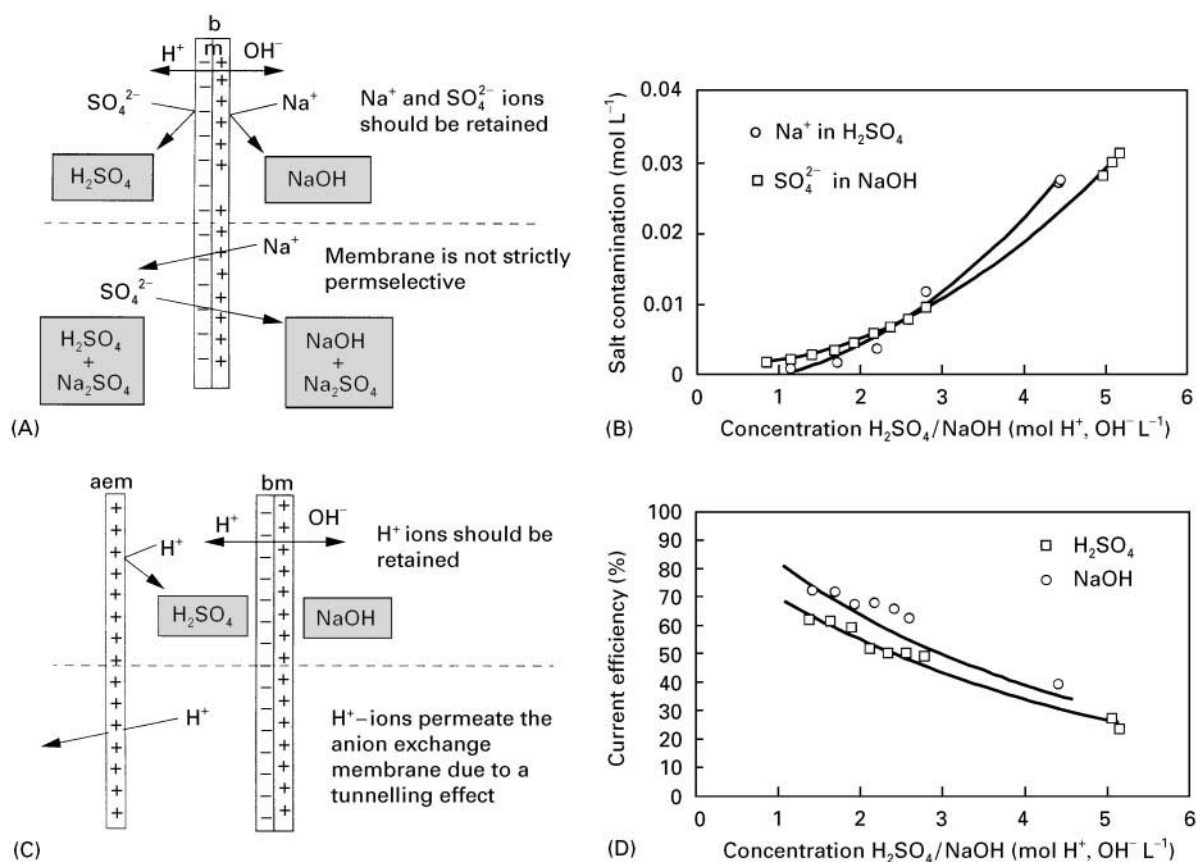

Figure 4 Schematic diagram illustrating (A) the contamination of an acid and a base by salt to incomplete permeability of the cation and anion exchange layers of a bipolar membrane; (B) experimentally determined salt contamination as a function of the acid and base concentrations; (C) the decrease in current efficiency during the production of acids and bases due to the poor acid-blocking capability of the anion exchange membrane; (D) experimentally determined current efficiency as a function of the produced acid and base concentration.

exchange membrane rather freely. The same is true for the hydroxide ions which can permeate the cation exchange membrane. The net result of the process is that protons and hydroxide ions generated in the bipolar membrane neutralize each other. The proton and hydroxide fluxes and thus the current efficiency depend on the concentration, as shown in Figure 4D. With increasing acid and base concentration, the current efficiency decreases rapidly.

Application of Bipolar Membranes

One interesting application of bipolar membranes is the production of caustic soda. Currently, caustic soda is produced as a co-product of the products of chlorine by electrolysis of salt. The worldwide demand for polyvinyl chloride and other chlorinated hydrocarbons has led to the development of a large market for chlorine. Because of environmental problems caused by chlorinated hydrocarbons and the disposal of polyvinyl chloride wastes, the demand for

chlorine is steadily decreasing, however, and it can be expected that the demand for caustic soda will soon exceed that produced in the chlorine alkaline electrolysis. Thus interest in alternative processes for obtaining caustic soda is increasing. Electrodialytic water dissociation with bipolar membranes is one of the more promising techniques for the future large scale economic production of caustic soda. However, today's bipolar membranes produce caustic soda with some salt contamination. The production of NaOH and H₂SO₄ from the corresponding salts has been investigated in great detail. Test results obtained in laboratory studies are shown in Figure 4. These tests were carried out with a 1 mol L⁻¹ solution Na₂SO₄ feed at room temperature and an applied current density of 0.1 A cm⁻². The test results indicate that up to three normal acid and base solutions can be achieved with a current utilization of 60–70%. However the produced acid and base are contaminated by salt and the salt contamination increases with increasing acid and base concentrations due to decreasing

selectivity of the bipolar membrane with increasing acid or base concentrations. Salt concentration can reach values in excess of 0.03 mol L^{-1} at 4 molar base or acid concentrations. To improve the overall efficiency of the electrodialytic dissociation processes and to obtain less salt contamination in the acids and base produced, better proton-blocking membranes have to be developed in addition to more selective bipolar membranes.

Fortunately, there are a large number of other potential applications of the electrodialytic water dissociation where the purity of the product, i.e. the produced acid or base, is not critical and traces of salts can be tolerated. Typical applications of bipolar membranes with large industrial relevance are:

- Recovery of acids and bases such as sulfuric, hydrochloric or hydrofluoric acid and sodium hydroxide from the salts generated in neutralization reactions
- The recovery of organic acids such as formic, acetic, citric, lactic and itaconic acid or certain amino acids from fermentation broths
- Adjustment of pH values in fermentation or chemical production processes without increasing the ion potential
- Regeneration of H_2SO_4 and NaOH from Na_2SO_4 obtained in industrial effluents, for example, in the production of viscose or regenerated cellulose
- Regeneration of acids and bases from scrubbers used to remove SO_2 , NO_x from contaminated air streams.

This list of potential applications of the electrodialytic water dissociation with bipolar membranes is not complete and as more efficient bipolar membranes become available, more applications will certainly be identified. In this outline three typical examples for the use of bipolar membranes are described in more detail.

Recycling H_2SO_4 and Dimethylisopropylamine from an Acid Scrubber

Alkaline or acid scrubbers are often used to remove components that are harmful to the environment, such as NO_x , SO_2 or certain amines from waste air streams. In these processes large amounts of acids or bases are consumed and salts are produced. In general, only dilute acids and bases are required in scrubbers. This makes the use of electrodialytic water dissociation with bipolar membranes a very suitable process to recover the acids or bases from the corresponding salts. The recovery of base from scrubbers used to remove SO_2 and NO_x from coal-burning power plants is described in detail in the literature.

Another similar application is the recovery of dimethylisopropylamine removed from a waste air stream by a sulfuric acid scrubber. This type of waste air stream is generated when aluminium casting moulds are made from a sand/epoxy resin mixture by injecting dimethylisopropylamine in a mixture with air as catalyst to cure the resin instantaneously. The amine is not consumed in the process and is emitted in a waste air stream containing *ca.* $0.5 \text{ g amine per m}^3$ waste air. The amine can be recovered as amine sulfate in an acid scrubber, as indicated in Figure 5. The amine can then be regenerated by adding sodium hydroxide and distilled. The net result of the process, however, is the production of large amounts of sodium sulfate.

A complete recycling of the amine, the sulfuric acid and water is achieved without the production of a salt by combining the electrodialytic water dissociation with distillation. The process is illustrated in Figure 6. The waste air stream containing the amines is fed into an acid scrubber where the free amine is converted into amine sulfate. The effluent of the acid scrubber containing about 10% amine sulfate in a mixture with sulfuric acid is then fed into the electrodialytic water dissociation apparatus

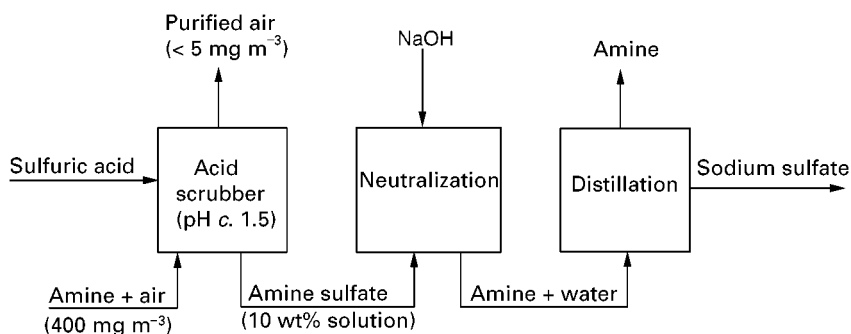

Figure 5 Schematic diagram illustrating a conventional process for recovering an amine from a contaminated air stream using an acid scrubber.

Figure 6 Schematic diagram illustrating the recovery of dimethylisopropyl amine from a waste air stream by combination of acid scrubber, diffusion dialysis and electrochemical water dissociation using bipolar membranes and distillation.

containing bipolar membranes and anion and cation exchange membranes in alternating series between two electrodes. Here the amine sulfate is converted to the free amine while the sulfate ions form sulfuric acid which is recycled to the acid scrubber. The amine–water mixture is distilled to recover the amine and the water is recycled to the electrochemical unit. Thus, the process allows complete recovery of the amine from a waste air stream by combination of an acid scrubber and electrochemical water dissociation.

Production of Itaconic Acid in a Continuous Fermentation Process

One of the more promising applications of bipolar membranes is the adjustment of the pH value of fermentation solutions to recover the organic acids from the spent medium. As an example the production of itaconic acid is described below.

Conventionally, itaconic acid is produced by a batch fermentation process. During fermentation the pH value shifts towards lower values due to the production of the acid. To avoid product inhibition the pH is maintained at a high level by addition of sodium or ammonium hydroxide which form soluble salts with the produced itaconic acid. At the end of the fermentation processes, the free acid is recovered from the spent medium by lowering the pH value by adding sulfuric acid. The adjustment of the pH values in the fermenter as well as in the spent medium is not only costly, but also creates salts mixed with the desired product and thus further purification steps are required. By applying bipolar membrane technology the production of salts can be eliminated and the itaconic fermentation can be carried out more ef-

ficiently in a continuous process, as illustrated in the production scheme depicted in **Figure 7**. The flow scheme shows a fermenter combined with an electrochemical unit fitted with bipolar membranes. The fermenter is continuously fed with substrate and its constituents passed through an ultrafiltration unit. The retained biomass is recycled to the reactor while the product containing filtrate is fed to the middle cell of a three-compartment electrochemical unit. In this cell the solution will be depleted of the ions. The cations, i.e. sodium or ammonium ions, permeate the cation exchange membrane and form, with the OH^- ions generated in the bipolar membrane, NaOH which is concentrated and then fed back into the bioreactor to adjust the pH value. The anions, i.e. the itaconate ions, permeate the anion exchange membrane and form, with protons generated at the bipolar membrane, the itaconic acid which is then concentrated and precipitated. Thus, the itaconic acid is produced in a continuous process without the addition of acids or bases, i.e. without the production of additional salts.

The Electrochemical Production of Sodium Methylate by Methanol Dissociation

Bipolar membranes may be used not only for the electrochemical dissociation of water. They can also be applied for the dissociation of alcohol and thus for the production of alcoholates, as illustrated in the following example. Methanol, like water, is both a weak base and a weak acid. Its dissociation constant, however, is somewhat less than that of water. Thus, sodium methanolate can be efficiently produced from methanol and sodium acetate in nonaqueous media by the use of bipolar membranes

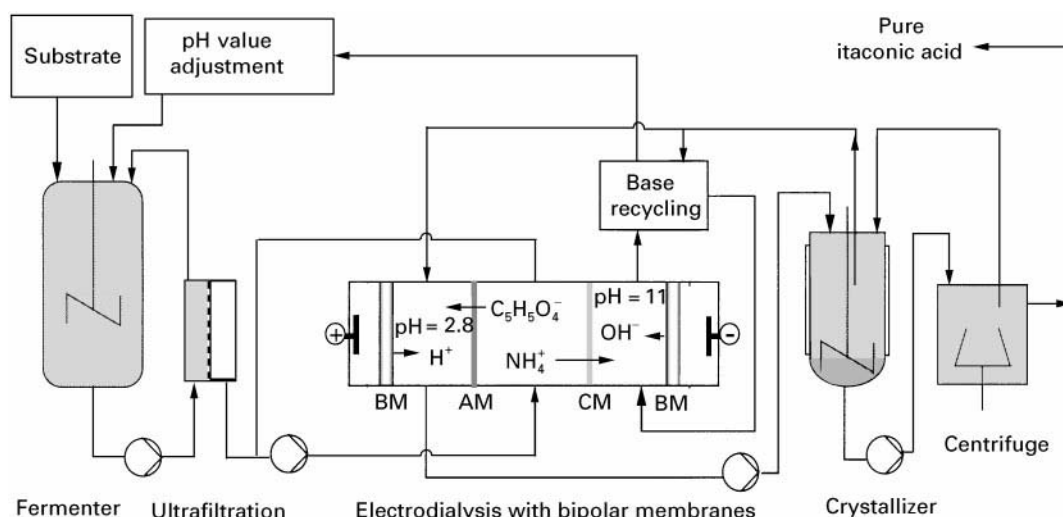

Figure 7 Schematic diagram illustrating a continuous fermentation process for the production of itaconic acid without further addition of acids or bases using bipolar membranes.

according to the reaction scheme illustrated in Figure 8, which shows a bipolar membrane electrodialysis stack consisting of two compartment cell systems in a repeating unit between electrodes. Water-free methanol and sodium acetate are fed into the cell formed by the bipolar and the cation exchange membrane which is directed towards the cathode while water-free methanol is passed through the other cell. Under the driving force of an electrical potential gradient, methanol is split in the bipolar membrane into protons and CH_3O^- ions which react with sodium ions migrating from the sodium acetate-

containing cell to form CH_3ONa . The acetate ions recombine on the other side of the bipolar membrane with the protons which were produced simultaneously with the CH_3O^- ions in the bipolar membrane to form acetic acid. Thus, sodium acetate and methanol are converted into sodium methanolate. The current efficiency decreases with increasing methylate concentration due to proton transfer from the acetic acid-containing compartment through the bipolar membrane to the sodium methanolate-containing cell. But all in all the process seems to be technically feasible.

Figure 8 Schematic diagram illustrating the electrodialytic production of sodium methanolate from methanol and sodium acetate in bipolar membranes containing a two-compartment cell unit.

Conclusions

The mechanism of water dissociation in bipolar membranes can be rationalized by a hypothesis which postulates a catalytic reaction between a weak base and water. Based on this hypothesis, very stable chemical and thermal bipolar membranes can be prepared and operated efficiently at current densities in excess of 0.1 A cm^2 . The process has many potential applications. There are, however, still a multitude of problems to be solved. Some are related to the poor selectivity of the bipolar membranes and poor acid-blocking capability of the anion exchange membranes; others are caused by the lack of application know-how and practical experience.

Introduction

The concept of completing both a reaction and separation in a single process unit has motivated research into the development of catalytic membrane reactors. For example, it has long been recognized that palladium metal has the capacity both to permeate hydrogen and to promote a variety of reactions. Thus, harnessing both of these features in a single device seemed a logical combination. In the mid 1960s, Wood and co-workers demonstrated that the dehydrogenation of cyclohexane to cyclohexene could be increased if the hydrogen produced was removed from the reaction vessel through semipermeable palladium walls. In this case, the palladium walls also acted to catalyse the dehydrogenation reaction. A membrane reactor of this type is illustrated in Figure 1.

In Russia, Gryaznov conducted much of the research that followed. Starting in the late 1970s, Gryaznov began publishing his results on the use of palladium membrane reactors both to produce and to recover hydrogen from a myriad of dehydrogenation reactions. In the dehydrogenation reactions, hydrogen leaves the reactor by permeating through the semipermeable membrane. However, reactors can also be used in reactions where hydrogen or other reaction products enter the reaction chamber by penetration through the membrane. The commonest classes of reactions that have been successfully influenced by the use of membrane reactor technology

are listed in Table 1. Details relating to the large volume of research reported are provided in the Further Reading section. None of these membrane reactors are in commercial use. But some – the selective oxidation of methane, for example – are the subject of a very large industrial research effort. If successfully developed, this process would change the feedstock basis of a number of petrochemical processes.

Most research on the development of membrane reactors involves the use of these devices to shift equilibrium-limited reactions (often dehydrogenations). The thermodynamic equilibrium of the reactants and products at the temperature and pressure of the reaction determine the conversion achievable in any given reaction. For dehydrogenation reactions, increasing temperature and decreasing pressure promote an enhanced reaction. Unfortunately, each of these solutions has an associated cost. Increasing the reaction temperature typically results in a reduced

Introduction

The concept of completing both a reaction and separation in a single process unit has motivated research into the development of catalytic membrane reactors. For example, it has long been recognized that palladium metal has the capacity both to permeate hydrogen and to promote a variety of reactions. Thus, harnessing both of these features in a single device seemed a logical combination. In the mid 1960s, Wood and co-workers demonstrated that the dehydrogenation of cyclohexane to cyclohexene could be increased if the hydrogen produced was removed from the reaction vessel through semipermeable palladium walls. In this case, the palladium walls also acted to catalyse the dehydrogenation reaction. A membrane reactor of this type is illustrated in Figure 1.

In Russia, Gryaznov conducted much of the research that followed. Starting in the late 1970s, Gryaznov began publishing his results on the use of palladium membrane reactors both to produce and to recover hydrogen from a myriad of dehydrogenation reactions. In the dehydrogenation reactions, hydrogen leaves the reactor by permeating through the semipermeable membrane. However, reactors can also be used in reactions where hydrogen or other reaction products enter the reaction chamber by penetration through the membrane. The commonest classes of reactions that have been successfully influenced by the use of membrane reactor technology

are listed in Table 1. Details relating to the large volume of research reported are provided in the Further Reading section. None of these membrane reactors are in commercial use. But some – the selective oxidation of methane, for example – are the subject of a very large industrial research effort. If successfully developed, this process would change the feedstock basis of a number of petrochemical processes.

Most research on the development of membrane reactors involves the use of these devices to shift equilibrium-limited reactions (often dehydrogenations). The thermodynamic equilibrium of the reactants and products at the temperature and pressure of the reaction determine the conversion achievable in any given reaction. For dehydrogenation reactions, increasing temperature and decreasing pressure promote an enhanced reaction. Unfortunately, each of these solutions has an associated cost. Increasing the reaction temperature typically results in a reduced

Figure 1 Schematic of a membrane reactor using hydrogen-permeable palladium membranes to shift the equilibrium of the dehydrogenation reaction cyclohexane to cyclohexene.

Table 1 Reaction classes that may be amenable to membrane reactor technology

Reaction class	Example	Role of membrane
Hydrogenation	$C_2H_2 + H_2 \rightarrow C_2H_4$ in presence of C_2H_4	Controlled addition of hydrogen
Hydrogenolysis	Cyclopentadiene + $H_2 \rightarrow$ cyclopentene + cyclopentane	Controlled addition of hydrogen
Dehydrogenation	Cyclohexane \rightarrow benzene + 3H_2	Remove hydrogen to shift equilibrium limitation
Partial oxidation	Butane + $O_2 \rightarrow$ maleic anhydride	Recovery of intermediate product of control reactant at addition rate to promote formation of intermediate product
Esterifications	$R-OOH + CH_3OH \rightarrow R-O-O-CH_3 + H_2O$	Selective water removal to shift equilibrium limit without loss of reactant
Syn gas	$CH_4 + \frac{1}{2}O_2 \rightarrow CO + 2H_2$	Selective oxidation of methane
Oxidative coupling	$2CH_4 + O_2 \rightarrow C_2H_4 + 2H_2O$	Selective oxidation of methane

catalytic selectivity for the desired product. Reducing pressure comes at the cost of adding a diluent to the reactor, paying for the additional capital to handle this component and paying the price of downstream separation.

Figure 2 provides a schematic representation of the behaviour of a conventional reactor and a theoretical membrane reactor. The conventional data are for a highly active butane dehydrogenation catalyst operating at 1 atm total pressure (pure normal butane feed). In the conventional system, the selectivity of the catalyst degrades rapidly at temperatures that are just beginning to promote reaction. Thus, the catalytic yield (defined as the product of conversion and cata-

lytic selectivity) goes through a pronounced maximum. Incorporation of an appropriately designed membrane into the reactor system results in the removal of hydrogen from the system. The catalytic selectivity does not appear to be influenced by this process, but the conversion of butane to butene is enhanced by the reduction in the hydrogen partial pressure. Thus, the yield of the membrane reactor system is markedly improved.

The ability to operate at acceptable conversions while maintaining very high catalytic selectivity is a strong driving force for the use of membrane reactor technology. By operating in a high selectivity region, the production of by-products that can act as catalyst poisons is minimized. This results in a longer catalyst life between regenerations and reduced waste production.

Possible Membrane Configurations

Incorporation of a reaction and separation zone in a single process unit allows for a variety of possible configurations. The optimum design of the equipment is closely tied to the reaction conditions and the ability of the membrane material to serve as a catalyst. Several of the more common configurations are shown in Figure 3. For illustrative purposes, the dehydrogenation of a compound to form hydrogen will be considered. The hydrogen is removed from the reaction zone to increase the equilibrium conversion. Similar configurations can be employed for the other reactions listed in Table 1. As described below, these configurations represent the most frequently employed designs, however, the list is not exhaustive and new configurations are developed and patented regularly.

Figure 2 Influence of product hydrogen removal on the dehydrogenation of butane. Based on pure butane feed with 1.1 atm total pressure. Continuous line, conventional reactor; dashed line, membrane reactor.

Figure 3 Common membrane reactor configurations. (A) Catalytic membrane; (B) membrane tube packed with catalyst; (C) membrane-assisted batch reactor.

Catalytic Membrane

One of the earliest catalytic membrane configurations employed was that of the reactive tube. In this configuration, the material used to construct the tube fulfills both the roles of separation medium and catalyst. Few materials have this special capability. Palladium is one. Palladium has the ability to transport hydrogen through the matrix by a process of adsorption, dissociation, diffusion, and then reassociation on the low pressure side. Palladium is also a reasonable catalyst for many of the reactions detailed in Table 1, especially hydrogenation and dehydrogenation reactions. Thus, using this material to achieve both functions was an obvious consideration.

Transport can only be achieved through a chemical potential driving force of the hydrogen from the reaction zone to the separation zone. Such a driving force has been established with the use of a sweep gas on the permeate side to keep the hydrogen concentrations low. The sweep gas may either be inert or reactive with the hydrogen. Inert sweep gases offer the advantage of being simple to employ. Unfortunately, to achieve a partial pressure difference across the membrane, the sweep gas rate must be high and the permeated hydrogen is recovered as a dilute component in the sweep gas.

Reactive sweep gases offer other engineering possibilities and challenges. The use of air as a sweep gas in catalytic dehydrogenation membrane systems has been reported. At dehydrogenation temperatures (300–600°C), oxygen can react with hydrogen to form water. This reaction is highly exothermic. In contrast, the dehydrogenation reaction is endothermic. Thus, thermal matching of the heat released by the hydrogenation of oxygen and the heat consumed by the dehydrogenation reaction would allow for an isothermal system. Because the hydrogenation reaction is rapid, the effective partial pressure on the permeate side of the membrane can be maintained near zero.

Catalytic membrane systems require that the membrane material be stable for both reaction and separation and that it operates well in both modes simultaneously.

Packed Tube

Optimization of a single material for both catalytic and separative functions is challenging. Few materials have the ability to transport the desired component and act as a catalyst for the desired reaction. Furthermore, even for materials that possess both characteristics, precise matching of the rates of reaction and

transport is difficult. To overcome these limitations, a packed membrane tube configuration has been employed. In such a configuration, a catalyst is packed in the bore of a tubular membrane. Reactants are fed into the catalyst zone and products have the potential to be transported through the membrane walls and out of the reaction zone. This configuration offers tremendous flexibility in the selection of the catalyst and membrane to be used. Both homogeneous and heterogeneous catalysts have been employed in this configuration.

Membrane-assisted Batch Reactor

The membrane-assisted batch reactor is most frequently considered for implementation because it requires the smallest process modification from traditional catalytic reactors. In this configuration, a membrane unit is added in the recycle line of a batch reactor. In so doing, the membrane has the capacity to selectively remove a product component or to selectively add a reactant. It has the advantage of allowing the pressure or temperature of the membrane and reactor unit to be controlled independently. Therefore, the properties of the membrane can be varied to optimize the separation achieved.

Membrane-assisted configurations suffer from the inability to remove product components completely as they are produced. This limits the conversion to values that are lower than those that are theoretically possible in the other configurations considered.

Available Membranes

The development of catalytic membrane reactors is limited by the availability of membranes capable of controlling the reaction environment that are stable at reaction conditions. A brief review of transport through membranes is provided and then the additional membrane requirements are summarized. Figure 4 provides a schematic of a membrane employed for the transport of a gaseous component.

Transport of a component through a solid is only possible if there are differences between the chemical potential of the component on the two faces of the solid. For gas-phase systems that operate at moderate pressures and can be considered to be ideal, transport can be described by:

$$\text{Flux}_i = P_i(p_{\text{Hi}} - p_{\text{Li}})/l \quad [1]$$

where P_i is the permeability of component i through the membrane, p_{Hi} is the partial pressure of component i on the high pressure side, p_{Li} is the partial

Figure 4 Schematic of transport through a solid.

pressure of component i on the low pressure side and l is the membrane thickness.

Thus, the difference in the partial pressure of the component to be transported controls the rate of transport. A high partial pressure driving force can be produced through:

- high total pressure on the feed side
- high concentration of the component of interest on the feed side
- low total pressure on the permeate side (using a vacuum)
- very low concentration of i on the permeate side using a very high dilution ratio of sweep gas

The rate at which a component is transported through a solid is defined as the flux of the component, (eqn [1]). To facilitate the comparison of a variety of materials, the properties of the material (permeability) have been separated from the process conditions (membrane thickness, pressures and concentrations). For equivalent process conditions, the material with the highest permeability will have the fastest transport.

The selectivity of a membrane for any pair of gases (A, B) is usually defined by the term $\alpha_{A/B}$, equal to the ratio of the gas permeabilities:

$$\alpha_{A/B}^* = P_A / P_B \quad [2]$$

For membrane reactors, membranes with high selectivities are required, so only the required component enters or leaves the reactor.

Specific Membranes

Certain materials have the ability to transport a single component with the complete exclusion of all others. Transport of hydrogen and oxygen through two of these materials is reviewed here.

Metals (hydrogen) Palladium and some of its alloys have the ability to transport hydrogen while

completely excluding all other compounds. The permeation of hydrogen through metals is a multistep process involving:

- chemisorption of hydrogen on to the metal surface
- dissociation of the hydrogen
- dissolution of the atomic hydrogen from the surface into the bulk of the metal
- diffusion across the metal layer
- the desorption from the bulk of the metal to the surface
- reassociation
- desorption of molecular hydrogen from the metal surface

The diffusion of atomic hydrogen across the metal layer is typically the rate-limiting step. Therefore, the transport of the hydrogen can be modelled using a Fickian diffusion equation.

Alloys of palladium have proven effective for the transport of hydrogen. Pure palladium undergoes a phase transformation in the presence of hydrogen at moderate temperatures, and a density change ensues. Even though these changes are small, they are sufficient to produce a brittle, cracked and non-selective material after only a few cycles. Therefore, few of the membranes evaluated are pure palladium and most commercial metallic hydrogen purifiers are prepared from a palladium/silver alloy containing 23% silver.

A significant limitation to the use of palladium membranes is their strong susceptibility to poisoning by sulfur compounds and CO compounds frequently found in the hydrocarbon streams of interest. Research into the development of more resistant materials is underway. However, the improved resistance has so far been attained at the cost of permeability. This issue must be resolved before these membranes can be used in the chemical process industry.

Nonporous ceramics (oxygen) Ceramic membranes have been developed which will selectively transport hydrogen or oxygen. Hydrogen has been shown to be transportable through nonporous silicon dioxide. While the transport rates are extremely slow, the selectivity to hydrogen transport is infinite, just as in defect-free palladium. Silicon dioxide has the advantage of being more resistant to the presence of sulfur compounds that act as poisons for palladium. Nevertheless, the challenge of forming this material into extremely thin layers has limited its use. Perhaps as preparation techniques continue to improve, the use of this material for the highly selective transport of hydrogen will be re-examined.

Nonporous ceramics have also been used for the transport of oxygen. Oxide-conducting materials, in-

cluding stabilized zirconia, have been used in membrane reactors. These membranes can successfully transfer oxygen while barring the transport of all other compounds. Current limitations relating to the temperatures required for operation are discussed in subsequent sections.

Nonspecific Membranes

Commercial utilization of membranes has relied almost exclusively on the use of nonspecific membrane materials. These materials have the ability to transport one component of a gas mixture in preference to a second. However, they are permeable to all components to at least some degree. Therefore, unlike palladium, which can act as a perfect separator, these membranes transport all stream components. The properties of both porous ceramics and polymeric membranes will be considered here.

Porous ceramics Porous ceramic membranes, with pore sizes ranging from a few nanometers to several microns, have been produced and are commercially available. These membranes separate by size exclusion. For the separation of gases and low molecular weight liquids, Knudsen diffusion is typically employed. For gases, Knudsen diffusion occurs for pore sizes of about 4–100 nm. For systems operating under the Knudsen diffusion regime, the separation of two molecules can be defined as:

$$\alpha_{A/B} = (MW_B/MW_A)^{0.5} \quad [3]$$

Thus, high degrees of separation selectivity are only possible if the molecular weight difference between the two components is large. These materials have been employed for the separation of hydrogen from hydrocarbon streams. The ideal separation selectivity for hydrogen over butane, for example, is 5.8. Thus, a small but measurable separation can be achieved.

The microporous nature of these membranes allows them to have very high transport rates, as compared to nonporous palladium or ceramic materials. Yet, the separation achievable is limited.

Polymers The final category of membrane materials to be considered is polymers. Polymeric membranes are employed for the separation of gas streams, the recovery of organic vapour from air, the separation of mixtures of organic liquids and filtration of particles from aqueous streams. Nonporous polymeric membranes have been considered for membrane reactor applications. Nonporous polymeric membranes separate on the basis of sorption of the component into

the polymeric matrix, diffusion across and desorption from the low pressure side.

Polymers offer several advantages when compared with the porous ceramics. For many gas pairs, the inherent selectivity of the polymeric membrane is substantially higher than that of a Knudsen diffusion-controlled ceramic. The polymeric membranes are also easier to prepare in high surface per volume modular configurations, resulting in a considerably lower price. Recent estimates put the price of commercial polymeric membranes at well under \$10 per square foot membrane area, installed. In contrast, ceramics may cost 10 times as much.

Many applications of membrane reactors, including dehydrogenation of hydrocarbons, hydrogenations and partial oxidation reactions are high temperature reactions. Conventional polymeric membranes do not have either the chemical or thermal stability to be successfully used in these reactions. However, recent advances have provided materials that can be processed using conventional solvent-based techniques and are later cross-linked to provide the chemical and thermal resistance necessary for membrane reactor applications. New polyimide-based materials provide such characteristics.

Polyimides that are thermally stable to 300°C for extended periods have been reported. When incorporated in a membrane reactor for the dehydrogenation of butane, the system performance increased markedly. With no membrane, conversions of 22% were achieved. Following addition of the membrane to the integrated system, the conversion increased to over 30%.

The development of chemically stable polymeric materials provides an opportunity to influence liquid-phase organic reactions.

Applications

While the use of membranes to influence catalytic reactions has been explored in great detail, few systems have been employed commercially. Some of the possible reasons for this slow adoption are listed below. Nevertheless, a few materials are produced through the use of membrane reactor technology. Gryaznov, for example, has reported the production of vitamin K using a single-step process utilizing a membrane reactor. The membrane was employed to control the hydrogenation of a mixture of quinone and acetic anhydride to form vitamin K. The membrane reactor process resulted in a 95% yield using an external hydrogen pressure of 1 atm. The conventional process required several processing steps and resulted in only 80% yield. This membrane reactor process is reported to be employed commercially in Russia.

Current Limitations

Some of the more important technical issues that have limited the implementation of membrane reactor technology are detailed below. In addition to technical problems, economic considerations are a concern. For many of the systems considered (Table 1), commercial production facilities using conventional reactor technology are available. If membrane reactors are to supplant these existing systems, the economic benefit must be substantial. Furthermore, the cost of the membrane reactor system must be only marginally higher than the conventional system. For most reactions, this is not currently the case.

Need for Pressure Drop

When one considers the use of membrane reactor technology for the selective removal of a product component (such as in dehydrogenations), the design of the membrane will be governed by the need for a partial pressure difference of this component. To increase the equilibrium conversion, these systems are run at low pressure with a goal of complete removal of the component as it is produced. Thus, the partial pressure of the product component is nearly zero in the reaction zone. For transport to occur, the partial pressure on the permeate side must be lower. Several techniques have been employed to attain partial achievement of these goals. These include high volumes of sweep gas on the permeate side; vacuum on the permeate side; and transforming the system to a batch reactor with continuous removal of the product component. In the last case, the partial pressure on the feed side is maintained at some finite level, and additional conversion is achieved by long residence times.

Sweep gas The use of high sweep gas ratios (nitrogen or argon is commonly employed in the laboratory) is effective in reducing the partial pressure of products in the reaction zone and enhancing conversions. For nonspecific membranes, it has been shown that two processes reduce the partial pressure of products: transport of the product from the reaction zone to the separation zone, and transport of sweep gas from the separation zone to the reaction zone. This latter process can occur because the membrane is nonselective and the partial pressure gradient of the sweep gas drives the transport. As the sweep gas permeates into the reaction zone, it acts as a diluent and provides a mechanism for an increase in the percentage conversion in the reactor. Unfortunately, the downstream separations required in these systems are significant and the economics are less favourable than simply mixing the diluent with the reactants in a conventional reactor.

Vacuum permeate An alternative method to produce a pressure drop is the use of a vacuum on the membrane permeate. This has been shown to be highly effective in laboratory settings. However, the economics are not favourable for the large scale production of inexpensive components. Nevertheless, vacuum permeate systems may prove viable for small, high value-added systems.

Batch versus continuous Continuous reactor systems are preferred; they require less down time and have higher production rates than batch systems of similar size. However, as previously detailed, if the role of the membrane is to remove a product component, the available partial pressure difference is limited and the process will always be working with a very limited pressure drop that will require very large membrane areas. Batch and semi-batch processes allow the system to develop some limited partial pressure difference before membrane separation is attempted.

Membrane Degradation

The stability of the membrane is another important consideration. Ideally, for integrated systems, the membrane should be stable in all possible reaction environments: catalyst activation, normal reaction, catalyst regeneration and any thermal cycling experienced upon transitions. This presents specific challenges for each system and there are few materials that can satisfy all of these requirements. Thus, special engineering solutions are necessary. Even if the membrane material can fulfil these specifications, the many components needed to produce a membrane reactor module may not.

Future Possibilities

Organic Separations

A great deal of research is currently focusing on the development of membranes (either polymeric, inor-

ganic, or hybrids of the two) for the selective separation of liquid organic mixtures. If this research is successful, it will allow for incorporation into liquid-phase membrane reactors.

Control of Reactant Addition for Intermediate Product Recovery

A second area of immense current research activity is the development of oxygen-permeable membranes to influence the conversion of methane to either methanol or syn gas. The goal in these processes is a mechanism for the conversion of natural gas to a transportable liquid that may be further converted to high valued products. Current research has shown that membranes can be developed and that the appropriate catalysts are available for these conversions. Many engineering challenges lie ahead. These membrane reactor processes operate in excess of 700°C (sometimes much higher). Sealing these ceramic membranes into a housing remains a limitation. Further, the thermal stresses, which develop when cycling from 25 to >700°C, may result in membrane damage. While these are complex problems, the incentive to succeed is large and numerous research efforts continue in this area.

Concentration Polarization

Introduction

All membrane separation processes are accompanied by a phenomenon called 'concentration polarization'

in which the composition at the feed-membrane interface differs from the composition in the bulk of the feed mixture. This gradient in composition is generated by the separation performed by the membrane and, as such, cannot be avoided. However, it is important to minimize the effects of concentration polarization because the gradient in composition reduces the separation performance of the membrane and increases the potential for membrane fouling.

Therefore, minimizing concentration polarization is one of the most important objectives in designing and engineering membrane separation systems.

Mathematical Description of Concentration Polarization

The velocity profile of a fluid flowing in a channel is not constant across the thickness of the channel, because of friction at the fluid-channel surface interface. The fluid velocity decreases as the distance from the channel surface decreases. The same phenomenon occurs in the channels of a membrane module, and the resulting velocity gradient adjacent to the feed side of the membrane is characteristic of all membrane processes. To facilitate mass transfer analysis, the velocity gradient is usually represented by a step function, and it is assumed that a stagnant boundary layer exists adjacent to the membrane. Any component permeating the membrane must first pass through the boundary layer as illustrated in Figure 1.

Although the boundary layer is stagnant in the direction of the feed bulk flow, the boundary layer is subject to convective flow perpendicular to the membrane surface which is generated by the permeate flux. The convective transport of a component into the boundary layer from the bulk solution is given by the product $v_p \cdot c_b$, where v_p (cm s^{-1}) is the convective velocity and c_b (g cm^{-3}) is the concentration in the bulk of the feed. The rate at which the same component leaves the boundary layer is $v_p \cdot c_p$, where c_p (g cm^{-3}) is the permeate concentration. In general, if separation is achieved, c_p does not equal c_b , and the convective flows into and out of the boundary layer, generate a mass imbalance. This imbalance then forms a concentration gradient in the boundary layer, and the concentration gradient increases until diffusion of the component down the concentration

gradient is sufficient to restore mass balance in the boundary layer.

At steady state, the sum of convective and diffusive transport in the boundary layer equals the amount permeated through the membrane. This steady state is expressed for each component by the equation:

$$v_p c_i - D dc_i/dx = J_i^w \quad [1]$$

where D ($\text{cm}^2 \text{s}^{-1}$) is the diffusion coefficient, x (cm) is the coordinate perpendicular to the membrane surface and J_i^w ($\text{g cm}^{-2} \text{s}^{-1}$) is the mass flux of i permeating through the membrane.

In liquid-phase separations (including pervaporation) concentrations are typically expressed as a weight fraction, $w_i = c_i/\rho$ where ρ (g cm^{-3}) is the density of the liquid. Assuming that the density of the feed is constant in the boundary layer:

$$v_p \cdot w_i \cdot \rho - D \cdot \rho \frac{dw_i}{dx} = J_i^w \quad [2]$$

and assuming that the feed density is equal to the density of the permeate:

$$J_i^w = w_p \cdot J_{\text{tot}}^w = w_p \cdot v_p \cdot \rho \quad [3]$$

where w_p (g g^{-1}) is the weight fraction of i in the permeate and J_{tot}^w ($\text{g cm}^{-2} \text{s}^{-1}$) is the combined mass flux of all components permeating the membrane. Combining eqns [2] and [3] and eliminating the density ρ gives:

$$v_p \cdot w_i - D \frac{dw_i}{dx} = v_p \cdot w_p \quad [4]$$

which, integrated over the thickness δ (cm) of the boundary layer, yields the polarization equation:

$$\begin{aligned} \frac{w_m - w_p}{w_b - w_p} &= \exp(v_p \cdot \delta / D) \\ &= \exp(v_p / k_{bl}) \\ &= \exp(J_{\text{tot}}^w / \rho \cdot k_{bl}) \end{aligned} \quad [5]$$

where w_m and w_b are the weight fractions of i at the membrane surface and in the bulk of the feed, respectively, and $k_{bl} = D/\delta$ (cm s^{-1}) is the mass-transfer coefficient in the boundary layer.

In gas-separation applications, concentrations are typically expressed as mole fraction n_i , which is equal

Figure 1 Schematic of the boundary layer adjacent to the membrane surface. If $c_p > c_b$, component is enriched in permeate. If $c_p < c_b$, component is depleted in permeate.

to the volume fraction, assuming the gas mixtures are ideal. Starting again with eqn [1], the mole fraction n_i can be substituted for c_i by using:

$$n_i = c_i \cdot 22\,400 \cdot T / (M_i \cdot p_f \cdot 273) \quad [6]$$

where $22\,400 \text{ (cm}^3 \text{ (STP) mol}^{-1})$ is the molar volume of an ideal gas, $T \text{ (K)}$ is the gas temperature, $M_i \text{ (g mol}^{-1})$ is the molecular weight of i , $p_f \text{ (bar)}$ is the feed gas pressure, and 273 K is the standard temperature. Also, the volume flux $J_i^v \text{ (cm}^3 \text{ (STP) cm}^{-2} \text{ s}^{-1})$ can be substituted for the mass flux J_i^w using:

$$J_i^v = J_i^w \cdot 22\,400 / M_i \quad [7]$$

Elimination of the term $M_i/22\,400$ gives:

$$v_p \cdot n_i \cdot p_f \cdot 273 / T - D \cdot p_f \cdot 273 / T \frac{dn_i}{dx} = J_i^v \quad [8]$$

Since $J_i^v = n_p \cdot J_{\text{tot}}^v$ and:

$$v_p = J_{\text{tot}}^v \cdot T / (p_f \cdot 273) \quad [9]$$

elimination of the term $p_f \cdot 273 / T$ gives:

$$v_p \cdot n_i - D \frac{dn_i}{dx} = v_p \cdot n_p \quad [10]$$

Figure 2 Schematic of the concentration polarization phenomenon. The concentration profiles in the boundary layer result from the separation achieved by the membrane. The type of concentration profile formed depends on the value of w_p relative to w_b (or n_p relative to n_b).

Integrating eqn [10] in the same way as eqn [4] gives:

$$\begin{aligned} \frac{n_m - n_p}{n_b - n_p} &= \exp(v_p \cdot \delta / D) \\ &= \exp(v_p / k_{bl}) \\ &= \exp(J_{\text{tot}}^v \cdot T / p_f \cdot 273 \cdot k_{bl}) \end{aligned} \quad [11]$$

where n_m and n_b are the mole (or volume) fraction of i at the membrane surface and in the bulk of the feed.

Eqns [5] and [11] describe the concentration profiles that develop in the boundary layer, as illustrated in **Figure 2**. Any component enriched in the permeate will be depleted in the boundary layer and any component depleted in the permeate will be enriched in the boundary layer.

Factors Determining the Extent of Concentration Polarization

The ratio of the concentration of a component at the membrane interface to the concentration in the bulk of the feed is called the ‘concentration polarization modulus’ and is a measure of the influence of concentration polarization on the separation process. The following expression for the modulus can be obtained from eqn [5]:

$$\frac{w_m}{w_b} = \frac{\exp(v_p / k_{bl})}{1 + E_o [\exp(v_p / k_{bl}) - 1]} \quad [12]$$

where $E_o = w_p / w_m$ is the intrinsic enrichment achieved by the membrane (and equal to the actual enrichment if concentration polarization were absent). An equation equivalent to eqn [12] but expressed in mole fractions can be derived from eqn [11].

Eqn [12] allows the concentration polarization modulus to be calculated as a function of v_p / k_{bl} for different values of the intrinsic enrichment factors, E_o . The ratio v_p / k_{bl} is a Peclet number and is a measure of the influence of convection relative to the influence of diffusion in the boundary layer. The results of this calculation are shown in the very informative **Figure 3**, which confirms that the concentration polarization modulus is smaller than 1 (boundary layer depletion) if the permeating compound is enriched in the permeate and larger than 1 (boundary layer build-up) if the permeating compound is depleted in the permeate. The concentration polarization modulus increasingly deviates from unity as the ratio v_p / k_{bl} increases, that is, as the flux through the membrane increases or as the turbulence

Figure 3 Concentration polarization modulus, w_m/w_b , as function of v_p/k_{bl} for a range of values of the intrinsic enrichment factor E_o . Lines calculated through eqn [12]. This figure shows that compounds that are enriched by the membrane ($E_o > 1$) are more affected by concentration polarization than compounds that are rejected by the membrane ($E_o < 1$).

of the feed fluid decreases. At high values for the ratio v_p/k_{bl} , the concentration polarization modulus, w_m/w_b , approaches the limiting value $1/E_o$. At this point, the boundary layer completely negates the separation power of the membrane permeation step. The concentration polarization modulus also increasingly deviates from unity as the intrinsic enrichment increasingly deviates from unity, that is, as the separation power of the membrane increases.

A striking feature of Figure 3 is the asymmetry with respect to enrichment and rejection. For example, when the term v_p/k_{bl} has a value of 10^{-1} , concentration polarization is essentially nonexistent for a component rejected by the membrane with an intrinsic enrichment E_o of 10^{-4} . On the other hand, concentration polarization is very severe for a component enriched by the membrane with an intrinsic enrichment E_o of 10^4 . The reason for this asymmetry is that the concentration polarization effect is generated by the difference in concentration between the permeate and the feed, $w_p - w_b = w_b(E - 1)$, where $E = w_p/w_b$ is the actual enrichment factor. It is clear that the absolute value of $w_p - w_b$ is significantly larger if $E > 1$ than if $E < 1$.

A second feature of the calculations shown in Figure 3 is that the concentration polarization modulus values are independent of the bulk concentration, w_b . This means that at a constant enrichment factor, E , the influence of concentration polarization is the same, no matter whether the component is present in the feed at a concentration of one part per hundred, one part per million, or one part per billion. Thus, concentration polarization does not necessarily affect components present at low concentrations more than components present at

higher concentrations. The primary requirement for significant concentration polarization effects is a high value for the enrichment factor, E . However, because E has an upper bound equal to $1/w_b$, a low feed concentration is a secondary requirement for severe concentration polarization effects. This confirms an empirical rule long held by membrane separation practitioners.

Transport Equations Incorporating Concentration Polarization

As pointed out in the previous sections, concentration polarization primarily affects membrane permeation by the change in composition at the membrane interface relative to the bulk of the feed mixture. To calculate the effect of concentration polarization on flux and separation, the transport equation for the membrane can be combined with eqn [5] or eqn [11] to arrive at a set of equations that predict the permeate flux and composition.

Ultrafiltration, nanofiltration and reverse osmosis are membrane processes in which a solute is separated from a solvent using a solute-rejecting membrane. Typically the permeate is essentially pure solvent, free of the solute. A simple but very effective transport equation developed for this situation is given below.

The pure solvent flux J_{solvent}^w ($\text{g cm}^{-2} \text{s}^{-1}$) of the membrane is given by:

$$J_{\text{solvent}}^w = \Delta P / R_m \quad [13]$$

where ΔP (bar) is the pressure difference applied across the membrane and R_m ($\text{bar cm}^2 \text{s g}^{-1}$) is the membrane resistance to the solvent. When a solute is present, the driving force for permeation is reduced by the osmotic pressure difference between the feed at the membrane interface and the permeate, $\Delta\pi_m$ (bar), therefore:

$$J_{\text{solvent}}^w = (\Delta P - \Delta\pi_m) / R_m \quad [14]$$

Eqn [14] is called the 'osmotic pressure model', in which the osmotic pressure is a measure of the thermodynamic work required to produce solvent from a solvent-solute mixture. Assuming that the permeate solute concentration is negligible:

$$\Delta\pi_m = a \cdot w_m^n \quad [15]$$

where a is a constant and n is an exponent equal to approximately 1 for low-molecular-weight solutes,

Figure 4 Solvent flux as a function of applied pressure as calculated from eqn [17]. The flux observed with solvent-solute mixtures is always less than the pure solvent flux. The deviation increases with increasing applied pressure, increasing solute concentration, and decreasing mass-transfer coefficient in the boundary layer.

but equal to 2 or higher for macromolecular solutes. Combining eqn [15] with eqn [5] and assuming $w_p = 0$ gives:

$$\Delta\pi_m = a \cdot w_b^n \cdot \exp(n \cdot J_{\text{solvent}}^w / \rho k_{bl}) \quad [16]$$

and:

$$J_{\text{solvent}}^w = (\Delta p - a \cdot w_b^n \cdot \exp(n \cdot J_{\text{solvent}}^w / \rho k_{bl})) / R_m \quad [17]$$

From eqn [17] it is clear that an increase in the flux J_{solvent}^w leads to an exponential increase in the osmotic pressure and that the flux will increase less than linearly with the applied pressure. This means that any increase in driving force ΔP will be negated at least in part by the increase in osmotic pressure. The general effect of pressure on flux predicted by eqn [17] is illustrated in **Figure 4** and is in agreement with the vast majority of experimental data. As can be seen from **Figure 4**, the flux observed with solvent-solute mixtures is always less than the pure solvent flux, and the deviation increases with increasing applied pressure, increasing solute concentration and decreasing mass transfer coefficient in the boundary layer. **Figure 4** also shows that at higher applied pressures the flux becomes essentially independent of the applied pressure. This is often observed in ultrafiltration applications and is referred to as the limiting flux. Eqn [17] predicts that under 'limiting flux' conditions the flux is independent of

the membrane resistance, which also has been confirmed experimentally.

Gel Layer Formation

When the solute is a macromolecular compound such as a protein or a polymer, there is the possibility that the solute concentration at the membrane interface exceeds the gel concentration, w_g , at which concentration the solution is no longer a fluid. A gel layer thus forms at the membrane interface which creates an additional resistance to the permeation flux which consequently decreases. The flux continues to decrease until the solute concentration at the membrane interface equals the gel concentration, at which point steady state is reached. The flux at that point can be obtained from eqn [5]:

$$J_{\text{limit}}^w = \rho \cdot k_{bl} \cdot \ln \left(\frac{w_g - w_p}{w_b - w_p} \right) \quad [18]$$

and because w_p is typically close to zero:

$$J_{\text{limit}}^w = \rho \cdot k_{bl} \cdot \ln(w_g/w_b) \quad [19]$$

The steady-state flux J_{limit}^w is called the 'limiting flux' because any increase in applied pressure will just result in a thicker gel layer and not in a higher flux. From eqn [19] it can be seen that the limiting flux as predicted by the gel layer model is independent of the applied pressure as well as the membrane resistance. Additionally, eqn [19] predicts a straight-line plot of J_{limit}^w versus $\ln(w_b)$ with a slope equal to $-\rho \cdot k_{bl}$. All these predictions have been confirmed in a vast number of ultrafiltration experiments. Interestingly, the osmotic pressure model also predicts a limiting flux with the same attributes.

Approaches to Minimize Concentration Polarization

The primary method of reducing the negative influence of concentration polarization is to maximize the mass-transfer coefficient in the boundary layer. Usually the first method used is to increase the feed velocity. This has the drawbacks of a high feed-to-residue pressure drop and the requirement of long, thin modules, which have higher capital costs than shorter, larger-diameter modules. A more efficient approach is to choose optimized feed-spacer materials and/or to create non-linear feed channels which induce mass-transfer-enhancing vortices. More complicated methods used for a feed mixture with a high viscosity and/or a high membrane fouling

potential employ spinning membranes or vibrating modules.

Introduction

Although haemodialysis (HD) as a therapy for uraemia (kidney failure) was first described early in the 1900s, its widespread use did not occur until the 1950s. At this time, Travenol Laboratories (now Baxter International) unveiled the 'coil' dialyser ('artificial kidney') in which tubes composed of cellophane membranes were wound around a support structure and immersed in a recirculated dialysis solution. Relative to contemporary models, the mass transfer efficiency of this type of dialyser was extremely poor, due to high mass transfer resistances in all three compartments (blood compartment, membrane, and dialysate compartment). In the early 1960s, solution mass transfer resistances were decreased with the introduction of parallel flow dialysers, in which sheet membranes were formed in a stacked configuration. The improvement in dialysate-side mass transfer with these dialysers was particularly large because the dialysis solution contacted the membrane under flow conditions as opposed to the semi-batch operation of the coil dialyser. In addition, the membranes used in these devices were thinner in structure, providing less diffusive resistance than earlier versions. Although the earliest manufactured parallel flow dialysers were not disposable, design improvements permitted the production of disposable units by the late 1960s.

The last truly major development in haemodialysers occurred more than 30 years ago when the hollow fibre artificial kidney was developed. Blood compartment mass transfer was reduced further with this design due to the high shear rate that could be achieved in the annular space of the hollow fibre. Additional benefits of the hollow fibre artificial kidney included an enhanced ability to control trans-

membrane pressure (see below) and a lower extracorporeal blood volume. This type of dialyser is now used in virtually all HD treatments.

On a global basis, approximately 800 000 patients receive chronic haemodialysis therapy for the treatment of end-stage renal disease (ESRD) and this population is growing at a rate of 8–10% per annum. This figure represents approximately 85% of the ESRD population, with the remaining patients receiving peritoneal dialysis. Numerous dialysis membrane and haemodialyser manufacturers are situated around the world, with the vast majority based in the three largest markets: United States, Western Europe and Japan.

The Haemodialysis Procedure

In addition to the dialyser, the other fundamental component of a HD system is a dialysis machine, which serves a number of purposes. First, it is equipped with a roller pump that delivers blood, usually at a rate of 200–500 mL min⁻¹, from the patient to the dialyser and back to the patient. Second, the dialysis machine prepares dialysate by mixing ('proportioning') water and a concentrated bicarbonate solution in such a ratio that the dialysis fluid produced is the same as that prescribed by a physician to meet the needs of an individual patient. The typical dialysate flow rate is 500–800 mL min⁻¹ and its major constituents are sodium, potassium, calcium and bicarbonate. The pathophysiology of uraemia is such that during the period between dialysis treatments, potassium levels in the plasma rise while calcium and bicarbonate levels fall. Consequently, the concentration of potassium in the dialysate is typically lower than that in the plasma at the beginning of the procedure while dialysate calcium and bicarbonate concentrations are typically higher. The third major function of the dialysis machine is to provide an accurate measurement of transmembrane pressure (TMP) in the dialyser, which is defined as the difference between the average pressure in the blood and

potential employ spinning membranes or vibrating modules.

Introduction

Although haemodialysis (HD) as a therapy for uraemia (kidney failure) was first described early in the 1900s, its widespread use did not occur until the 1950s. At this time, Travenol Laboratories (now Baxter International) unveiled the 'coil' dialyser ('artificial kidney') in which tubes composed of cellophane membranes were wound around a support structure and immersed in a recirculated dialysis solution. Relative to contemporary models, the mass transfer efficiency of this type of dialyser was extremely poor, due to high mass transfer resistances in all three compartments (blood compartment, membrane, and dialysate compartment). In the early 1960s, solution mass transfer resistances were decreased with the introduction of parallel flow dialysers, in which sheet membranes were formed in a stacked configuration. The improvement in dialysate-side mass transfer with these dialysers was particularly large because the dialysis solution contacted the membrane under flow conditions as opposed to the semi-batch operation of the coil dialyser. In addition, the membranes used in these devices were thinner in structure, providing less diffusive resistance than earlier versions. Although the earliest manufactured parallel flow dialysers were not disposable, design improvements permitted the production of disposable units by the late 1960s.

The last truly major development in haemodialysers occurred more than 30 years ago when the hollow fibre artificial kidney was developed. Blood compartment mass transfer was reduced further with this design due to the high shear rate that could be achieved in the annular space of the hollow fibre. Additional benefits of the hollow fibre artificial kidney included an enhanced ability to control trans-

membrane pressure (see below) and a lower extracorporeal blood volume. This type of dialyser is now used in virtually all HD treatments.

On a global basis, approximately 800 000 patients receive chronic haemodialysis therapy for the treatment of end-stage renal disease (ESRD) and this population is growing at a rate of 8–10% per annum. This figure represents approximately 85% of the ESRD population, with the remaining patients receiving peritoneal dialysis. Numerous dialysis membrane and haemodialyser manufacturers are situated around the world, with the vast majority based in the three largest markets: United States, Western Europe and Japan.

The Haemodialysis Procedure

In addition to the dialyser, the other fundamental component of a HD system is a dialysis machine, which serves a number of purposes. First, it is equipped with a roller pump that delivers blood, usually at a rate of 200–500 mL min⁻¹, from the patient to the dialyser and back to the patient. Second, the dialysis machine prepares dialysate by mixing ('proportioning') water and a concentrated bicarbonate solution in such a ratio that the dialysis fluid produced is the same as that prescribed by a physician to meet the needs of an individual patient. The typical dialysate flow rate is 500–800 mL min⁻¹ and its major constituents are sodium, potassium, calcium and bicarbonate. The pathophysiology of uraemia is such that during the period between dialysis treatments, potassium levels in the plasma rise while calcium and bicarbonate levels fall. Consequently, the concentration of potassium in the dialysate is typically lower than that in the plasma at the beginning of the procedure while dialysate calcium and bicarbonate concentrations are typically higher. The third major function of the dialysis machine is to provide an accurate measurement of transmembrane pressure (TMP) in the dialyser, which is defined as the difference between the average pressure in the blood and

dialysate compartments. Fluid removal requirements are quite patient-specific in this patient population such that both the rate and total volume of plasma water ultrafiltration need to be controlled accurately. Accurate control of ultrafiltration is achieved by continuous monitoring of dialyser TMP, which essentially is an ultrafiltration surrogate for a membrane of specific hydraulic permeability. Finally, monitoring components of the dialysis machine safeguards against potentially catastrophic events, such as air embolism or a massive blood leak related to a membrane defect.

Classification of Uraemic Solutes

In the properly functioning human kidney, plasma water and blood solutes are removed by ultrafiltration and convection, respectively. Solutes of molecular mass less than approximately 40 000 Da have essentially unrestrained passage through the glomerulus, the kidney's filtration unit. As such, the clearance of these solutes approximates to the plasma water ultrafiltration rate, which is about 120 mL min^{-1} for humans of normal size. By definition, ESRD is associated with absent or minimal native kidney function. As a result, blood solutes normally removed by the above filtration mechanism are retained in the blood stream with a resultant several-fold increase in their plasma concentrations.

The classification of uraemic solutes is typically based on molecular mass and three well accepted classes currently exist (Table 1). The first category, simply called 'small solutes', is comprised of nitrogenous compounds of molecular mass less than 200 Da. These solutes are by-products of protein metabolism and include the compounds urea (molecular mass 60 Da) and creatinine (113 Da), which are commonly measured in clinical medicine. The second category, referred to as 'middle molecules', consists of a diverse group of molecules in the 200 to 2000 Da range. Although this class has been widely studied from an experimental perspective, a represen-

tative solute, which is clinically measurable, has not yet been identified. Low molecular mass peptides and proteins (molecular masses 2000 to 40 000 Da) are the most recently identified class of uraemic toxins. The plasma concentrations of these compounds are typically increased 50–100-fold in ESRD. Recently, a specific toxin in this class, β 2-microglobulin (β 2M: molecular mass 11 800 Da), has been identified as a causative factor in the development of dialysis-related amyloidosis, a deposition disorder specific to the ESRD population.

Dialyser Specifications

Contemporary hollow fibre dialysers have nominal surface areas ranging from 1.0 to 2.2 m^2 , although the trend in clinical practice is to use devices at the upper end of this range. Both the length (approximately 23 cm) and inner diameter (i.d.: usually 200 μm) of hollow fibres used for clinical HD are fairly standard. The i.d. parameter represents a compromise between the desirable characteristics of a short diffusive pathlength and high shear rate with a small i.d., and a low axial pressure drop and hydraulic resistance with a large i.d. fibre. On the other hand, the variation in wall thickness is considerable, with values ranging from 6 to 55 μm . (See below for an expanded explanation.) Based on the surface area of the dialyser, the total number of fibres comprising the dialyser ranges approximately from 7000 to 12 000.

Extracorporeal Therapy Modes Used in ESRD Patients (Figure 1)

In a typical haemodialysis procedure, although transmembrane mass transfer occurs predominantly by diffusion, a modest degree of convective mass transfer is also achieved in association with the ultrafiltered plasma water. However, the recent recognition of β 2M and other low molecular mass proteins as important uraemic toxins has prompted interest in using dialytic therapies with increased convective removal capabilities for these poorly diffusible solutes. In haemodialysis, the total ultrafiltration volume and net ultrafiltration rate are determined by the degree to which a patient's plasma volume needs to be reduced and the duration of the treatment. (The total ultrafiltration requirement is dictated by the amount of fluid ingested by the patient in the period between dialysis treatments.) The total volume of plasma water ultrafiltered is approximately 3–4 L, resulting in a typical net ultrafiltration rate of $15\text{--}20 \text{ mL min}^{-1}$.

As a means to augment convective solute removal, haemofiltration (HF) was developed by Henderson,

Table 1 Classification of ureamic solutes

<i>Solute class</i>	<i>Molecular mass range (Da)</i>	<i>Examples</i>
Small solutes	< 200	Urea Creatinine
Middle molecules	200–2000	Appetite suppressant Osteoblast inhibitor
Peptides/proteins	2000–40 000	AGE-peptides β 2-Microglobulin Parathyroid hormone

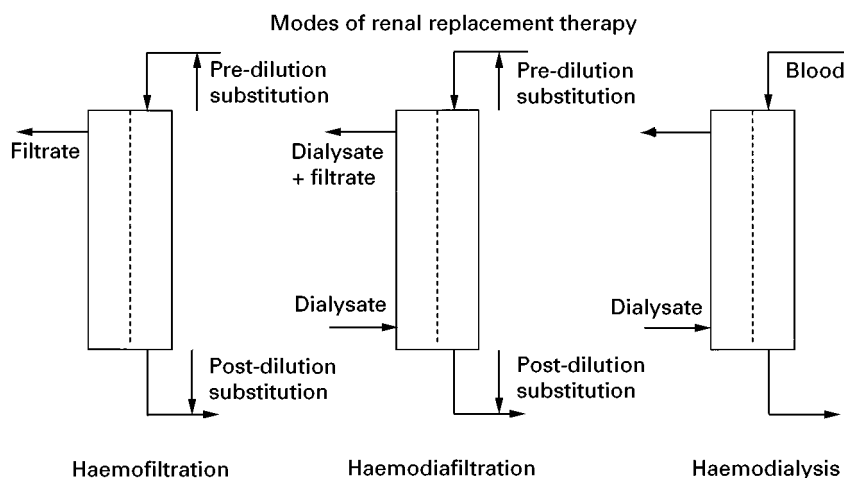

Figure 1 Extracorporeal therapy modes used in end-stage renal disease.

Lysaght and colleagues in the early 1970s. This is a purely convective therapy in which no dialysate is used but an ultrafiltration rate that far exceeds the net ultrafiltration requirements of the patient is employed. As plasma water is typically ultrafiltered at an absolute rate of at least 100 mL min^{-1} (6 L h^{-1}) in HF, the much lower net ultrafiltration rate required for fluid removal from the patient is achieved by 'replacing' most of the ultrafiltrate with a bicarbonate-based solution. For the large volume of intravenous-quality 'replacement fluid' that is required, the filtrate produced by sequential ultrafiltration of dialysate is used. This 'on-line' mechanism, in which the dialysate precursor of the replacement fluid is produced by the same HD machine that performs the HF treatment, allows very high volumes of ultrafiltrate to be produced. In HF, only dialysers with very high hydraulic permeability (see below) are used.

Although HF is a significant improvement over HD with respect to relatively large sized uraemic toxin removal, the absence of diffusion renders it only a marginal therapy with respect to small solute removal. To overcome this deficiency of HF, Canaud and colleagues approximately 15 years ago first employed online haemodiafiltration (HDF). As its name implies, this therapy is essentially a HD/HF hybrid in which both dialysate flow and high ultrafiltration rates are used. At present, HDF offers the broadest solute removal spectrum of all dialytic therapies.

Permeability Classification of Dialysis Membranes

Although numerous classification schemes have been proposed, HD membranes are traditionally classified according to water flux. The clinical parameter used to characterize the water permeability of a dialy-

ser is the ultrafiltration coefficient (K_{UF} : $\text{mL h}^{-1} \text{ mmHg}$). In fact, the only dialyser classification scheme recognized by the United States Food and Drug Administration is based on water permeability, with low and high permeability dialysers having K_{UF} values of < 8 and $\geq 8 \text{ mL h}^{-1} \text{ mmHg}$, respectively. The water permeability of a dialyser is usually derived from *in vitro* experiments in which bovine blood is ultrafiltered at varying transmembrane pressure. Based on a commonly used model which assumes that a membrane is composed of parallel cylindrical pores, the flux of plasma water through each pore is dependent on the fourth power of the radius so that small changes in mean pore size have a very large effect on water permeability.

A common misconception relating to dialyser performance is the assumption that a membrane's solute removal capabilities are necessarily correlated with its water permeability. Based on a model in which a membrane has N (straight) cylindrical pores (per unit surface area) of radius r , diffusive solute flux can be expressed as:

$$\phi = \lambda D \rho \Delta C / t \quad [1]$$

where λ is the solute partition coefficient, D is solute diffusivity, ρ is membrane porosity, ΔC is the transmembrane concentration gradient, and t is membrane thickness. (While the partition coefficient is essentially unity for solutes such as urea and creatinine, larger solutes with incomplete access to the membrane pores have λ values that are less than one.) Membrane porosity is a function of both pore size and number:

$$\rho = N \pi r^2 \quad [2]$$

For all dialysis membranes, small solutes such as urea and creatinine have free pore access ($\lambda = 1$). Therefore, small solute transport is highly dependent on membrane porosity. As eqn [2] indicates, one membrane with a large number of relatively small pores and a second membrane with a small number of relatively large pores can have equivalent porosities. Although the small solute transport properties of these two hypothetical membranes would be equivalent, the flux (water permeability) properties would greatly differ. This difference is explained by the strong dependence of ultrafiltrate flux on membrane pore size, described above.

Polymeric Composition of Dialysis Membranes

From a relatively simplistic perspective, dialysis membranes can be divided into those comprised of cellulose-based material and those comprised of synthetic materials.

Cellulosic Dialysis Membranes

The monomeric subunit of cellulosic membranes is cellobiose, a naturally occurring saccharide found in plants. Chemically, cellobiose is a ringed structure richly endowed with hydroxyl groups. The interaction of complement cascade products with these hydroxyl groups is felt to be responsible, at least partly, for the relatively pronounced complement activation observed when unsubstituted cellulosic membranes contact blood. For the past several years, a major objective among manufacturers has been the development of modified (substituted) cellulosic membranes in which a certain fraction of these hydroxyl groups are replaced with other moieties. The substitution groups diminish the degree of complement activation by at least three different mechanisms. One mechanism is the replacement of a large percentage of the hydroxyl groups with acetate groups. In the first substituted cellulosic membrane, cellulose (di)acetate, approximately 70–80% of the hydroxyl groups on the cellulosic backbone were replaced with an acetate group. Most likely because this modification eliminates a large fraction of the active surface sites for interaction with complement components, an attenuation of the intense complement activation seen with unmodified cellulose was achieved. This membrane modification also resulted in a moderate increase in pore size, yielding a slightly higher water permeability and broader solute removal spectrum for cellulose acetate in comparison to unsubstituted cellulosic membranes of similar surface area. Extrapolation of this process to total replacement of the

hydroxyl groups resulted in the cellulose triacetate fibre characterized by further attenuation of complement activation and higher water permeability.

A second cellulosic substitution mechanism is the replacement of a relatively small percentage (less than 5%) of the hydroxyl groups with a bulky chemical group, which sterically reduces the degree of interaction between complement activation products and the membrane. Examples for which this strategy is employed are Hemophan® (tertiary amine substitution) and synthetically modified cellulose (SMC; benzyl substitution group).

The evolution in cellulosic membranes has resulted in a wide spectrum of biocompatibility and flux profiles. If complement activation and neutropenia are used as the major biocompatibility criteria, regenerated cellulose is the least biocompatible while cellulose triacetate is the most biocompatible, with the other modified cellulosic membranes having intermediate profiles. However, characterization of the flux properties of these membranes is not as straightforward. For dialysers of comparable surface area, a simplistic approach is to report K_{UF} values in the following ascending order: regenerated cellulose < Hemophan®, synthetically modified cellulose < cellulose acetate < cellulose triacetate. In this simplistic scheme, a 1.5 m² dialyser having a regenerated cellulose, Hemophan®, or SMC membrane generally falls in the low flux category ($K_{UF} < 8 \text{ mL h}^{-1} \text{ mmHg}$) while comparably sized dialysers having cellulose acetate and cellulose triacetate membranes fall in the midflux ($K_{UF} 10\text{--}20 \text{ mL h}^{-1} \text{ mmHg}$) and high flux ($K_{UF} > 20 \text{ mL h}^{-1} \text{ mmHg}$) categories, respectively. However, this simplistic categorization scheme breaks down in several respects. High flux cellulose acetate membranes have now been produced and cellulose triacetate dialysers of low water permeability ($K_{UF} 9.5 \text{ mL h}^{-1} \text{ mmHg}$) are also available. Finally, the recent development of unmodified cellulosic and cellulose acetate membranes having relatively low water permeability but solute removal capabilities that include $\beta 2\text{M}$ further confounds this classification scheme and provides additional examples of a dissociation between water and solute flux.

Synthetic Dialysis Membranes

The monomeric subunits of the various synthetic membranes individually vary and all differ significantly from cellobiose. The absence of surface hydroxyl groups on synthetic membranes is one factor responsible for the reported differences in complement activation between synthetic membranes and either unsubstituted cellulosic membranes or modified cellulosic membranes of low permeability.

Subsequent to the introduction of the AN69® (sulfonated polyacrylonitrile) membrane in the early 1970s, numerous additional synthetic membranes have been introduced for clinical use. Similar to AN69®, polysulfone and polyamide were brought to the market for use in both high flux HD and haemofiltration. One obvious reason accounting for the use of these membranes in a haemofiltration mode is their significantly larger pore size and hydraulic permeability than regenerated cellulose membranes. The other reason relates to the structural differences between the synthetic and unsubstituted cellulosic membrane groups. Cellulosic membranes have relatively thin walls (generally in the 6–15 µm range) which have a uniform (symmetric) composition across their entire thickness. Although the relative thinness of cellulosic membranes is desirable with respect to diffusive solute transport, this same characteristic renders many cellulosic membranes unable to withstand the high transmembrane pressures required to perform convective therapies employing high ultrafiltration rates. The synthetic membranes have thicker walls (20 µm or more) which may be structurally symmetric (e.g. AN69®, polymethylmethacrylate (PMMA)) or asymmetric (e.g. polysulfone, polyamide, polyethersulfone). In the latter category, a very thin 'skin' (less than 5 µm) contacting the blood compartment lumen acts primarily as the membrane's separative element with regard to solute removal while the remaining thickness (stroma) imparts mechanical strength. In turn, the composition of the stroma layer is quite variable for the various synthetic membranes. For the Fresenius polysulfone membrane, the stroma is relatively homogeneous with a sponge-like structure while the Gambro polyamide membrane has, adjacent to the skin, a sponge-like stroma layer which has progressively larger pores ('macrovoids' with a finger structure) in the radially outward direction. Finally, a new synthetic (polyethersulfone) membrane developed by Membrana GmbH (formerly Akzo Nobel) has a novel configuration consisting of a sponge-like stroma layer interposed between skin layers on both the inner (blood-side) and outer (dialysate-side) aspects.

In the production of synthetic membranes made of primarily hydrophobic polymers (polysulfone, polyamide, polyethersulfone), a hydrophilic additive (polyvinylpyrrolidone: PVP) acts as a polymer alloy. PVP is used to impart sufficient hydrophilicity to the membrane to allow clinical use and, as a wetting agent, modulates surface tension and viscosity within the pore structure during membrane formulation. This latter feature explains PVP's importance in determining the overall pore size distribution of synthetic membranes.

Although synthetic membranes are employed for both haemofiltration and high flux HD, it is in the latter mode that these membranes have found their widest application. Another synthetic membrane formulation was reported in the late 1980s with the introduction of low flux versions. Low flux polysulfone and PMMA have been used clinically for several years and recently a low flux version of a polyamide/polyethersulfone copolymer has been introduced.

Effect of Membrane Composition and Structure on Dialytic Solute Removal

Small Solute Removal

Small solute removal during HD occurs almost exclusively by diffusion. To quantify a particular membrane's diffusive capabilities, its mass transfer resistance is frequently used:

$$R_O = R_B + R_M + R_D$$

In the above equation, the overall resistance to diffusive mass transfer of a particular solute (R_O) has three components: blood compartment resistance (R_B), resistance due to the membrane itself (R_M) and dialysate compartment resistance (R_D). Minimizing the mass transfer resistance in the blood compartment primarily requires the use of relatively high flow rates (i.e. shear rates) that decrease unstirred layers. Dialysate-side mass transfer resistance is likewise decreased by increasing flow rate but optimal dialysate perfusion of fibre bundles is also a consideration. Although increasing dialysate flow rate may itself improve fibre bundle perfusion (see below), another mechanism by which this can be achieved is the inclusion of spacer yarns. These devices are spacing filaments placed external to the fibres and are designed to facilitate dialysate distribution and reduce channeling. The resistance related to the membrane itself actually has two components:

$$R_M = X_M/D_M$$

where X_M is the effective diffusion path-length for a solute and D_M is the solute-specific membrane diffusivity. This equation indicates that a decrease in membrane resistance can be achieved either by a decrease in membrane thickness or an increase in membrane diffusivity, the latter of which is influenced strongly by membrane porosity.

Middle Molecule Removal

Vitamin B₁₂ (molecular mass 1350 Da) is commonly used for *in vitro* characterizations of dialysers. However, due to its extensive binding to plasma proteins, this compound is not useful *in vivo*. In fact, the removal of uraemic solutes having molecular masses which fall in the classic middle molecule category has been difficult to quantify due to the lack of an easily measured *in vivo* surrogate molecule (cf. urea and creatinine for the small solute category). Because recent evidence suggests that uraemic appetite suppression is mediated by the retention of solute(s) in this size range, an understanding of removal mechanisms for middle molecules is important. Based on dialysis practices used in the 1960s and early 1970s (i.e. relatively low flow rates and thick, low permeability cellulosic membranes), diffusive middle molecule removal was so limited that any convective removal contributed relatively substantially to total removal. However, the situation is vastly different in contemporary HD, in which higher flow rates and dialyser membranes of significantly greater diffusive permeability for middle molecules are employed.

Low Molecular Mass Protein Removal

Recent interest in increasing the extracorporeal removal of β 2M has provided insight into the general mechanisms mediating the removal of low molecular mass proteins. A number of studies published in the past 15 years support several general conclusions. First, β 2M removal by low flux unsubstituted cellulosic membranes is usually negligible, although certain exceptions do exist. Second, the primary mechanism by which β 2M is removed during high flux HD varies widely among membranes. For certain membranes, such as AN69® and particularly PMMA, removal is achieved predominantly or solely by adsorption. At the other end of the spectrum is the cellulose triacetate membrane, for which adsorption is minimal and removal occurs primarily by diffusion. High flux polysulfone and unsulfonated PAN membranes have intermediate adsorptive characteristics and achieve transmembrane β 2M removal by a combination of diffusion and convection. Third, at least for the high flux synthetic membranes, use of convection-based therapies (HF and HDF) increases β 2M removal relative to standard (diffusion-based) HD. Although many clinicians consider β 2M to be surrogate for the low molecular mass protein class of uraemic solutes, this assumption has not been conclusively proved. Nevertheless, it is reasonable to use the abundant transport data available for β 2M to provide insight into the transport charac-

teristics of other low molecular mass proteins, such as complement activation products and cytokines.

Interaction Between Biocompatibility and Flux

Measurement of complement pathway by-products is one technique used to assess the inflammatory response elicited by exposure of blood to a dialysis membrane. However, numerous previous studies have failed to account for the fact that the clinically measured complement components (C3a and C5a) are low molecular mass proteins. Therefore, the concentration of these inflammatory mediators represents the net result of the simultaneous processes of generation and any dialytic removal that may occur. In this regard, complement activation products are similar to most uraemic solutes, for which the plasma concentration is determined by both generation and net removal. The corollary of this observation is that the permeability properties and not just the polymeric composition of a dialysis membrane must be considered when evaluating complement activation data. Recent data indicate that the relatively low levels of complement activation associated with high permeability synthetic membranes is at least partially related to their ability to remove, either by adsorption or transmembrane transport, the generated inflammatory mediators.

It is simplistic to limit the discussion about membrane biocompatibility to complement activation as a number of agents have been identified as potential inflammatory mediators in chronic HD patients. A list of these putative mediators appears in Table 2. Some of these compounds, such as Lipid A and LPS fragments, potentially have their origin in dialysate, a nonsterile fluid. Due to their relatively low molecular mass, these inflammatory mediators may undergo transmembrane passage and induce cytokine

Table 2 Inflammatory mediators

Mediator	Molecular mass (kDa)
Lipid A	2–4
Lipopolysaccharide (LPS) fragments	< 8
C3a	8.9
Granulocyte inhibitory peptide (GIP) II	9.5
C5a	11
Interleukin-1	17
Tumour necrosis factor (monomeric)	17
Factor D	23
Granulocyte inhibitory peptide (GIP) I	28
Tumour necrosis factor (trimeric)	55
Lipopolysaccharide (LPS)	> 100

Source: Lonneman G (1993).

production in the blood stream, either directly via an effect on mononuclear cells or indirectly via an effect on the alternative complement pathway. Conversely, the majority of the mediators that are potentially elicited in the blood, such as C3a and IL-1, may be simultaneously eliminated during high flux therapies by an adsorptive or transmembrane mechanism, as discussed above. Other investigations have confirmed that adsorption is also important in the removal of other inflammatory mediators, such as Factor D and cytokines.

Summary

Dialysers used in contemporary HD are equipped with a wide variety of membranes and within both the cellulosic and synthetic classes, water and solute flux properties vary widely. For small and middle-sized solutes, abundant clinical data point to the importance of membrane thickness in diffusive mass transfer. The removal of low molecular mass proteins may occur largely by adsorption for some high flux membranes, particularly those of hydrophobic synthetic composition. Because many of the mediators of inflammation in dialysis patients fall in this low molecular mass protein category, the biocompatibility of a particular membrane must be interpreted in conjunction with its permeability properties.

Introduction

Diffusion dialysis is a separation process in which an ion exchange membrane separates a source solution

and a receiving solution, usually water. Anion exchange membranes are notoriously permeable to acids, and diffusion dialysis exploits this property to separate acids from salts. A common application of diffusion dialysis is recovery of acids from waste metal pickling solutions, the strong acid solutions that are used to remove oxide coatings from metal parts before they are painted, galvanized or

production in the blood stream, either directly via an effect on mononuclear cells or indirectly via an effect on the alternative complement pathway. Conversely, the majority of the mediators that are potentially elicited in the blood, such as C3a and IL-1, may be simultaneously eliminated during high flux therapies by an adsorptive or transmembrane mechanism, as discussed above. Other investigations have confirmed that adsorption is also important in the removal of other inflammatory mediators, such as Factor D and cytokines.

Summary

Dialysers used in contemporary HD are equipped with a wide variety of membranes and within both the cellulosic and synthetic classes, water and solute flux properties vary widely. For small and middle-sized solutes, abundant clinical data point to the importance of membrane thickness in diffusive mass transfer. The removal of low molecular mass proteins may occur largely by adsorption for some high flux membranes, particularly those of hydrophobic synthetic composition. Because many of the mediators of inflammation in dialysis patients fall in this low molecular mass protein category, the biocompatibility of a particular membrane must be interpreted in conjunction with its permeability properties.

Diffusion Dialysis

Introduction

Diffusion dialysis is a separation process in which an ion exchange membrane separates a source solution

and a receiving solution, usually water. Anion exchange membranes are notoriously permeable to acids, and diffusion dialysis exploits this property to separate acids from salts. A common application of diffusion dialysis is recovery of acids from waste metal pickling solutions, the strong acid solutions that are used to remove oxide coatings from metal parts before they are painted, galvanized or

electroplated. Cation exchange membranes are permeable to bases, and this is utilized to recover NaOH from aluminium etching solutions.

Diffusion dialysis of acids through anion exchange membranes was reported as early as 1964, and was installed on an industrial scale by 1980. There have been many laboratory studies on membrane properties and transport of acid through such membranes. Therefore, the discussions that follow concerning the theory and practice of diffusion dialysis will focus primarily on acid transport through anion exchange membranes. Base dialysis is relatively new, and there is not a large body of knowledge about the mechanism of transport, design criteria and performance of that process. Until such information becomes available, it is reasonable to assume that the theory and practice of base dialysis parallels that of acid dialysis.

Since ion exchange membranes have an ionically charged polymeric structure, their discrimination between solutes is based on ionic charge. Anion exchange membranes are easily permeated by anions, but cations are rejected, because the positive ionic change of the membrane matrix repels the cations. Unlike other cations, hydrogen ions are an integral part of the water that pervades the membrane, and hydrogen ions seem to permeate by a different mechanism that avoids the rejection of the charged polymer structure. Anion exchange membranes transport acids while rejecting salts.

Figure 1 illustrates diffusion dialysis for recovery of HNO_3 from a solution also containing $\text{Fe}(\text{NO}_3)_2$. The anion exchange membrane is quite permeable to the NO_3^- ions, but an equivalent amount of cations must also pass through the membrane to maintain electroneutrality. Because of their double positive

charge, the Fe^{2+} ions are strongly rejected by the membrane, but the protons are transported rather easily. Thus, a useful separation of acid and salt is achieved.

Background and Theory

Transport in diffusion dialysis is described by Fick's law:

$$\text{Flux} = -U \Delta C \quad [1]$$

where ΔC is the concentration difference of the diffusing solute (the driving force for diffusion) and U is a mass transfer coefficient, expressed in units of length time⁻¹. Since the concentrations can be measured only in the bulk solutions, the measured value of ΔC is the driving force for diffusion through the membrane and the solution boundary layers next to the membrane. Therefore, an overall mass transfer coefficient U_o is needed to describe the observed flux. The reciprocal of the mass transfer coefficient is the diffusional resistance, and the diffusional resistances of the membrane and the adjacent liquid boundary layers are additive.

$$1/U_o = 1/U_m + 1/U_l \quad [2]$$

Values of U for a particular solute through a particular membrane are conveniently measured in a stirred cell with the membrane separating the source solution from the receiving solution, usually pure water. With sufficient stirring the resistance of the liquid can be minimized so that the measured value of U is essentially U_m . Acids permeate some anion exchange

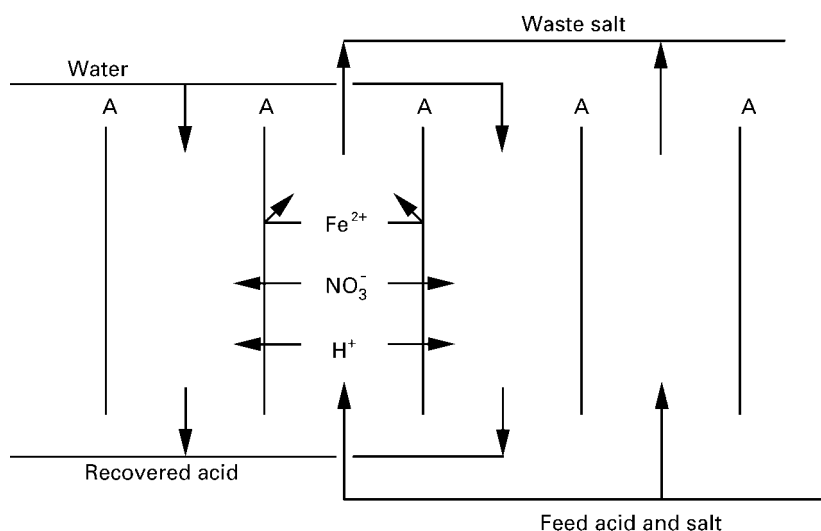

Figure 1 Diffusion dialysis to recover HNO_3 from pickling solution.

membranes rapidly, with U values of about 10^{-4} to $10^{-3} \text{ cm s}^{-1}$ while salts have U values of about $10^{-6} \text{ cm s}^{-1}$. Therefore, there is sufficient difference in the diffusion rates to achieve useful separations of acids from salts by diffusion dialysis.

Since solution velocities in commercial dialysers are slow, U_1 could be a significant part of U_0 . A rough idea of the resistance in the boundary layer can be estimated by examining the elements of the equation for diffusive flux through a film of liquid:

$$\text{Flux} = -D \Delta C/z \quad [3]$$

where D is the diffusivity of the solute through the solvent, typically about $10^{-5} \text{ cm}^2 \text{ s}^{-1}$, and z is the thickness of the film of liquid through which diffusion occurs. Spacing between membranes in a commercial dialysis apparatus is somewhat less than 0.1 cm, so liquid film thickness z would probably be about 0.01 cm. Then $D/z = 10^{-3} \text{ cm s}^{-1}$, which is a U value for the liquid film of the same order of magnitude as the typical U values for dialysis membranes.

Consequently, both the membrane and the liquid films in contact with it are likely to contribute to the resistance to diffusion in a real dialysis application, even at rather high solution velocities.

Transport of solvent through dialysis membranes can be great enough to influence diffusion dialysis performance. Osmotic forces provide a driving force to transport solvent from the dilute solution to the concentrated solution. However, the diffusing solute can drag along solvent, both in the solvation shells of the ions and by convection, in the direction opposite to that of normal osmosis. Further, osmotic pressures are caused by the concentration difference of nondiffusing solutes across the membrane, the values of which can be difficult to determine. Consequently, even the direction of solvent transport can be difficult to predict in certain circumstances, and prediction of the rate of solvent transport is quite difficult.

Mathematical analysis of dialysis is rather simple if the assumptions are made that the overall value of U is independent of C and that solvent transport is negligible. There are two typical cases that are usually encountered with dialysis in general or with diffusion dialysis.

Case 1 is an experiment done in an apparatus used to measure dialysis coefficients, i.e. U values. A sample of the membrane is placed between two chambers of equal volume in a stirred cell, with a surface area A exposed to both solutions. The source solution fills one chamber, and an equal volume V of pure water, the receiving solution, fills the other chamber. Because the volumes of the two solutions are equal, the concentration of the diffusing solute

decreases in the source solution at the same rate as it rises in the receiving solution on the other side of the membrane. The rate of concentration change, dC/dt , is related to the flux, volume and area of the membrane by the equations below. On the side containing the receiving solution:

$$dC/dt = \text{flux} \times A/V \quad [4]$$

and on the side containing the source solution:

$$dC/dt = -\text{flux} \times A/V \quad [5]$$

To integrate this equation, an expression is needed for flux in terms of concentrations on one side of the membrane. The appropriate expression can be obtained by material balance. Let C_s represent the concentration of the diffusing solute on the side with the source solution. Then the concentration of the diffusing solute in the receiving solution would be $C_r = C_0 - C_s$, where C_0 is the initial concentration of the source solution. Now an equation for solute flux can be written as follows:

$$\begin{aligned} \text{Flux} &= -U \times \Delta C = -U \times [C_s - (C_0 - C_s)] \\ &= -U \times (2C_s - C_0) \end{aligned} \quad [6]$$

The differential equation can be integrated to yield:

$$C_s = C_0(1 + e^{-2tUA/V})/2 \quad [7]$$

on the side of the source solution and:

$$C_r = C_0(1 - e^{-2tUA/V})/2 \quad [8]$$

on the side of the receiving solution.

The experiment described in case 1 is a useful technique for measuring values of U for a membrane. Sufficient stirring can reduce solution film resistance to negligible levels, and even volume changes are insignificant in short experiments. Volume changes and analytical inaccuracy can cause substantial errors if source solution concentrations are used in this determination, so determination of the U value should be based on the measured concentrations in the receiving solution.

Although the apparatus described in case 1 is useful for determining membrane properties, it is of limited commercial value as a separation process because no more than half of the diffusing solute can be removed when equal volumes are used on both sides of the membrane. A high degree of removal would require a volume of the receiving stream much larger than that of the feed, but that has limited commercial

appeal. A commercially useful separation can be achieved with countercurrent flow of the solutions through the dialyser.

Case 2 is an example of countercurrent flow of the solutions on opposite sides of the membrane. The system operates at steady state so that concentrations do not change with time, but they do change with position along the flow path of the solutions. To simplify the equations it will be assumed that there is no solvent transport through the membrane and that the source and receiving solutions have the same flow rate, F . When pure water is used for the receiving stream, the material balance is simply:

$$C_f = C_d + C_r \quad [9]$$

where the subscripts represent the feed, depleted and recovered streams respectively. The amount of solute transferred across the membrane is equal to the amount of solute appearing in the recovered stream:

$$UA \Delta C = FC_r \quad [10]$$

Because the flow rates are equal, the concentration change within a solution compartment is linear with respect to distance along the flow path, so the concentration difference across the membrane is equal to the arithmetic mean concentration difference:

$$\Delta C = (C_f + C_d - C_r)/2 \quad [11]$$

Combining this with the material balance equation yields:

$$\Delta C = C_f - C_r \quad [12]$$

which can be combined with the transfer equation:

$$UA(C_f - C_r) = FC_r \quad [13]$$

and rearranged to show the fraction of solute recovered:

$$C_r/C_f = U/(U + F/A) \quad [14]$$

In practice, the values for U are often expressed in the same units as the flow rate per unit area of membrane, $L h^{-1} m^{-2}$. For the diffusion of HCl from pickle liquor through Neosepta AFN anion exchange membrane, reported values of U are $8.6 L h^{-1} m^{-2}$ for HCl and $0.17 L h^{-1} m^{-2}$ for Fe, and a typical value for F/A might be $1 L h^{-1} m^{-2}$. With these values the HCl recovery would be $8.6/(8.6 + 1) = 0.9$, and the Fe leakage would be $0.17/(0.17 + 1) = 0.15$. Thus, 90% of the HCl is recovered, and 15% of

the Fe appears in the recovered acid. Leakage of Fe could be reduced to 8% by doubling the flow rates, but HCl recovery would drop to 81%.

The simplified equation developed above for countercurrent dialysis is only applicable when flow rates of both streams in the dialyser are equal. For those more general situations with unequal flow rates, the log-mean concentration difference would be used as the driving force in Fick's law.

Deviations from Simple Modelling

Osmotic forces play a key role in the water balance, and water transport through the membrane can invalidate the simple mathematical models described above. The following discussion is based on the recovery of acid from a steel pickling solution, which is a significant industrial application of diffusion dialysis. In the recovery of acid from a mixture with a metal salt the major driving force for osmosis is the difference in concentration of salt across the membrane. The osmotic flow of water can cause the volume of the receiving stream to decrease as much as 20% as it passes through a typical industrial dialyser. Therefore, a good mathematical model of diffusion dialysis should account for water transport through the membrane.

The presence of salt in the source solution can substantially affect the concentration of acid in the recovered stream. In diffusion dialysis of metal pickle liquors the source solution has two important components – the free acid that can diffuse through the anion exchange membrane rather easily and the metal salt that is rejected by the membrane because of repulsion of the metal cations by the fixed positive charge on the membrane matrix. There are numerous reports of countercurrent diffusion dialysis in which the acid concentration in the recovered stream is higher than the free acid concentration in the feed. Some writers have attempted to explain these observations in terms of osmotic removal of water from the receiving stream, but it seems more plausible that a concentration difference of the common anion produces a driving force for transport of protons through the membrane. That driving force is the Donnan potential (discussed in 'Membrane Separations: Donnan Dialysis') generated by the difference between the activity of anions in the two solutions. That potential difference provides a driving force for proton transport in addition to the driving force provided by the difference in concentration of the free acid.

Fick's law describes acid flux due to simple diffusion as the product of the driving force ΔC_A and the mass transfer coefficient for diffusion, U_A . A similar expression can be used to describe the acid

Figure 2 Diffusion dialysis of pure 4 mol L⁻¹ HNO₃ feed stream (continuous line) with a pure water-receiving stream (dotted line).

transport due to the concentration difference of the salt with a common anion, with ΔC_s as the driving force and U_s as the mass transfer coefficient. The total acid flux can be expressed as the sum of the flux due to individual driving forces as follows:

$$\text{Total acid flux} = U_A \Delta C_A + U_s \Delta C_s \quad [15]$$

This empirical equation was tested with published data by Edwards, who measured HNO₃ concentrations on both sides of a Tokuyama AFN membrane in a stirred cell. Graphs of data for three different starting compositions are shown in Figures 2–4. In each graph the data at the top connected by the continuous line show the reduction in concentration as acid diffuses from the source stream, and the data at the bottom show the increase in acid in the receiving

stream. Figure 2 shows simple diffusion of HNO₃, which is well described by the dotted line that was calculated by Fick's law with $U_A = 12.8 \text{ L h}^{-1} \text{ m}^{-2}$. But when NaNO₃ was added to the source solution, Fick's law with $U_A = 12.8 \text{ L h}^{-1} \text{ m}^{-2}$ (shown in Figure 3 by the dotted line) predicts a much slower appearance of acid than the data indicated. The equation for total acid flux with values of $U_A = 12.8 \text{ L h}^{-1} \text{ m}^{-2}$ and $U_s = 0.45 \text{ L h}^{-1} \text{ m}^{-2}$ shown by the dashed line gave a good correlation of the data. It is interesting to note in Figure 3 that the influence of the excess nitrate forced so much HNO₃ out of the source stream that its concentration fell below that in the receiving stream. The situation was reversed when NH₄NO₃ was placed in the receiving solution.

Figure 4 shows that the total acid flux equation with values of $U_A = 12.8 \text{ L h}^{-1} \text{ m}^{-2}$ and $U_s =$

Figure 3 Diffusion dialysis of 0.1 mol L⁻¹ HNO₃ and 5 mol L⁻¹ NaNO₃ feed stream (continuous line) with a pure water-receiving stream (dashed and dotted lines). Lines calculated as described in the text.

Figure 4 Diffusion dialysis of a 2.1 mol L^{-1} HNO_3 feed stream (continuous line) against a 4 mol L^{-1} NH_4NO_3 -receiving solution (dashed and dotted lines).

$0.45 \text{ L h}^{-1} \text{ m}^{-2}$ again described the data better than Fick's law and correctly showed that the appearance of acid in the receiving solution was retarded by the presence of nitrate in that solution. It should be emphasized that the total acid flux equation is empirical, but it does seem to be a useful way of accounting for the effects of salts on acid flux and would thus be useful for mathematical modelling of diffusion dialysis of acids.

Competing Processes

Diffusion dialysis, like most other membrane processes, must compete with other processes that can achieve the desired separation. Lime neutralization, sorption on ion exchange resins and bipolar membranes are competing processes for the treatment of waste acids from metal pickling. When disposal and replacement acid costs are low, lime neutralization is the most economical alternative. When the recovered acid can be used in a diluted form, sorption on ion exchange resins is attractive. When it is necessary to minimize discharge, bipolar membranes, though expensive, can be the preferred process. Diffusion dialysis offers the important advantages of very low operating costs and long membrane life that can exceed 5 years if clean, nonfouling feeds are used. Therefore, if diffusion dialysis can achieve the desired separation and if capital costs are tolerable, diffusion dialysis can be the process of choice for recovering waste acids.

Membranes for Diffusion Dialysis

Modern membranes for acid dialysis are made of anion exchange polymers which have an affinity for

acids and reject cations other than protons. The anion exchange membranes that are most permeable to acids seem to be those with a very high water content. The water content is important because the high electromobility of protons through water is attributable to a transfer mechanism that is not available to other cations. A proton can transfer from a hydronium ion to an adjacent water molecule by a mechanism which was first suggested by Grotthuss in 1806.

The major suppliers of diffusion dialysis membranes and devices are Asahi Glass, who make Selemin DMV, and Tokuyama Corporation who make Neosepta® AFN and AFX membranes. Since the membrane devices for diffusion dialysis are similar to those used in electrodialysis, any supplier of electrodialysis equipment is capable of supplying diffusion dialysis equipment as well. The supplier with the largest number of installations in the USA is Pure Cycle Environmental Technologies in Palmer, Massachusetts, and the largest supplier in Europe is Eurodia in Paris, France.

Membranes for base dialysis were parchmentized paper when the process was first developed in the 1930s. The early membranes had little selectivity between caustic and salts, but they effectively retained hemicellulose from rayon and viscose processes. Modern membranes for base dialysis are made of cation exchange polymer that rejects anions other than hydroxyl, presumably because of the Grotthuss mechanism of hydroxyl transport. The typical cation exchange membrane made for electrodialysis has low flux for base diffusion, but Tokuyama Corporation has made a special cation exchange membrane, Neosepta® CMX-SB, with acceptably high flux.

Design of Processes and Equipment

Industrial diffusion dialysis usually operates with countercurrent flow of the solutions on opposite sides of the membrane. Countercurrent flow produces the maximum concentration difference over the entire length of the membrane and allows recovery of a substantial portion of the most highly diffusive solute while minimizing the transport of the less diffusive solutes. Since fluxes in diffusion dialysis are relatively low compared to other membrane processes, the solution velocity across the membrane surface must also be slow in order to have enough residence time for adequate removal of the solute. Typical solution velocities in diffusion dialysis are about 1 cm min^{-1} . Convective effects due to density changes in the solutions can be important with such low velocities.

Dialysers for industrial applications must be robust, cleanable, efficient and economical. Industrial diffusion dialysers usually have flat sheet membranes with some type of spacer to keep the membranes apart and to form solution compartments. The membrane arrangement (without showing the spacers) and the directions of solution flows in a typical diffusion dialyser are shown in Figure 1. A single dialyser can contain hundreds of identical, vertically oriented membranes. Membranes and spacers have holes that are aligned to form manifolds, and each spacer has entry ports that connect the solution compartment to the appropriate manifold. This manifolding, which is also typical in electrodialysis, distributes the solution equally to the parallel compartments. The feed solution usually enters the bottom of the dialyser and the solvent usually enters at the top, as shown in Figure 1.

Solutions flowing through the industrial diffusion dialyser should be free of particulate matter, because the solution velocities are too slow to sweep out particles. The dialyser can be expected to perform maintenance-free for several years if the feed solution is clean and no precipitation occurs within the dialyser. A single filter on each supply line should suffice if the feed solution is inherently clean. However, primary and secondary filtration is recommended if particles are expected to be present in the feed because of the possibility of contamination during the cleaning or replacement of primary filter elements.

The low solution velocities that characterize diffusion dialysis cause extremely low pressure drops through dialysers, usually just a few kPa. Many dialysers can be fed in parallel from a single header tank positioned just above the dialysers. The solutions exiting the dialysers also enter a header tank with adjustable overflow levels. The header tanks should

have covers and filtered vents to avoid the entrance of dust. Transparent tanks or sight glasses positioned close together allow the operator to monitor visually the pressure drop through the dialyser. Density differences of the solutions should be considered in determining the actual pressure head.

In metal finishing plants the dialysis process is normally set up to run continuously to treat a small stream of the metal-laden acid in the pickling tank and return the recovered acid to the tank. This allows the dialysis to run as a steady-state process. The waste stream, which typically contains 10% of the acid and 90% of the metals from the feed, is usually neutralized to precipitate the metal as hydroxides for disposal or recovery.

It is important that the solution flow is uniformly distributed to all solution compartments that are fed in parallel. Density changes caused by solute transfer across the membranes are utilized to achieve uniform flow distribution. The feed solution, which has the highest density, enters the bottom of the dialyser and decreases in density as acid is removed. Osmotic water transport into this concentrated solution also contributes to the decrease in density. The receiving solution increases in density as it flows downward. The uniform gradation in density allows the solutions to approach plug-flow conditions in each solution compartment.

Entrapped gas can cause flow disruptions in the receiving solution compartments of acid dialysers. Water entering the top of the receiving solution compartments contains some dissolved gases (O_2 , N_2 , CO_2) that can form bubbles in the downward-flowing solution. Even if the water is not initially supersaturated with dissolved gases, the addition of solute diffusing across the membrane can lead to supersaturation within the receiving stream. The slow downward flow of solution is not sufficient to force the bubbles out the bottom of the dialyser, but it could hinder their rise in the compartments. Bubbles eventually reach such a large size that buoyancy forces exceed the forces of surface tension. Then the large bubbles rise and collect in the top of the compartment and eventually in the entry ports where they block off the flow of water into some of the receiving solution compartment. As more compartments become blocked, the solution velocity in the remaining compartments increases. But that increase in flow rate means that the residence time in those open compartments is shorter, so the performance of the dialyser deteriorates.

Removal of the dissolved gases from the water before it enters the dialyser is beneficial. Gases can be removed by heating the water in an open or vented tank, by application of a vacuum or by passing the

water through a nonwetting microfiltration device with a vacuum applied to the opposite side of the microporous membrane. Another remedy is periodically to reverse the flow of the receiving stream and force the bubbles out of the top of the dialyser into a vent tank. Flow reversal can be accomplished easily with a centrifugal pump situated in the line of the receiving solution at the entrance or exit to the dialyser. The header tanks must have sufficient surge capacity to accommodate the volume of the flow reversal. Flow reversal for a few seconds is sufficient – just long enough to displace any gas that has accumulated in the top of the receiving compartments and entry ports. These two remedies are often used together.

The heat of dilution of the acid can also cause problems of overheating in diffusion dialysis. Because the dialyser acts like a countercurrent heat exchanger, the heat released in the dialyser tends to become trapped inside. When the concentration of acid in the feed is high, the peak temperature, which occurs about halfway through the flow path, can be high enough to damage the membrane.

Limitations of Diffusion Dialysis

A necessary condition of dialysis is that the solute concentration in the recovery stream must be lower than in the feed stream in order to provide a driving force for diffusion. This is not a real limitation in applications where the diffusing solute is a waste that can be easily discarded. But this condition can be a limitation when the diffusing solute is the desired product, because the product is often recovered at a low concentration. Fortunately, the acid from steel pickling solution can be recycled to the pickling bath at the concentration at which it was recovered. Another limitation is that the nondiffusing solutes are left in the original solution in a slightly diluted state, which means that the waste volume can be considerable.

The selectivity of diffusion dialysis membranes for rejecting metal ions is influenced by the ionic charge on the metal ion. Metal ions with multiple positive charge are rejected more efficiently than ions with a single charge. However, zinc and some other metal ions form complexes with the anions of the acid. In HCl solutions, zinc forms ZnCl_3^- and ZnCl_4^{2-} complexes that behave as anions in the anion exchange membrane. These complex ions do not diffuse through the membrane as readily as Cl^- ions do, but they diffuse much faster than Zn^{2+} ions. However, zinc does not form a complex in H_2SO_4 solution, so zinc is rejected quite well in the sulfate system.

All of the halogens form complexes with some metals. Chloride complexes of Cu, Ga, Fe (ferric forms a much stronger chloride complex than ferrous), V and Zn have been reported. The existence of a chloride complex does not necessarily mean that HCl cannot be recovered from the metal salt by diffusion dialysis. Since the chloride complexes are rather bulky, they do not pass through the anion exchange membranes as easily as chloride ions do.

Applications

The first important industrial application for dialysis seems to have been for recovery of caustic from viscose, hemicellulose, wood-pulping solutions and textile-processing solutions. In the 1930s there were many patents describing dialysers that utilized diaphragms of parchmented paper and regenerated cellulose. Publications of that era described dialysis as a method for separating crystalloids (substances that form true solutions and are capable of being crystallized) from colloids (small particles in suspension).

By far the most important application for dialysis was begun during the 1940s when Dr. Willem Kolff discovered that treatment of blood by dialysis removed urea and other metabolic wastes, and he proceeded to develop the artificial kidney. The artificial kidney and other conventional dialysis processes are described in detail in 'Membrane Separations: Dialysis in Medical Separations'.

Conclusion

Diffusion dialysis utilizes membranes that contain ion exchange groups, and those were not available until the 1950s. Diffusion dialysis plants have been recovering and recycling acids in Japan since 1980, and many are being installed in the USA, particularly in metal-finishing facilities. Acids that have been recovered include HCl, HF, HNO_3 , H_2SO_4 and methanesulfonic. The recovered acid is sufficiently concentrated to be returned to the pickling tank, and the acid-free solution of metal salts requires considerably less base to precipitate the metal hydroxides. Recovery of mixed HF and HNO_3 from the pickling of stainless steel is important because these acids are expensive and cause severe pollution problems if they are discarded. Diffusion dialysis has been applied to the recovery of H_2SO_4 from aluminium anodizing baths where the trivalent aluminium cation is well rejected by the anion exchange membrane.

Base dialysis membranes have been used commercially for the recovery of NaOH from the waste

generated by the chemical milling of aluminium aircraft parts. Chemical milling is used to remove metal from aluminium parts, such as curved sections of wing or fuselage that are difficult to machine with mechanical devices. The part is dip-coated with a film of rubber, and then a selected portion of the rubber is stripped away to expose the metal surface. Then the part is immersed in boiling NaOH that rapidly and uniformly dissolves the metal from the exposed surface. The dissolved aluminium accumulates in the etch tank as NaAlO_2 , which must be discarded eventually. When the NaOH is removed from the solution by dialysis, the NaAlO_2 hydrolyses to $\text{Al}(\text{OH})_3$ and NaOH. The $\text{Al}(\text{OH})_3$ is recovered by filtration and sold as a pure product, and the released NaOH is returned to the etch tank along with the dialysed NaOH. Dialysis allows recovery of essentially all of the NaOH and completely eliminates the need for disposal of the waste etchant. An industrial installation of base dialysis has been operating success-

fully in a chemical milling plant in California since 1991.

Introduction

Donnan dialysis is a separation process that utilizes counterdiffusion of two or more ions through an ion-exchange membrane to achieve a separation. It can also be viewed as a continuous deionization process. For example, water softening can be done with a cation-exchange membrane. Hard water flows on one side of the membrane, and NaCl brine flows on the other side. Na^+ ions from the brine diffuse across the membrane and cause the Ca^{2+} and Mg^{2+} ions to diffuse in the opposite direction. Donnan dialysis is usually performed as a continuous, countercurrent process so that a substantial portion of a cation from a dilute solution could be concentrated into a small volume. Differences in the volumes and concentrations of the two solutions can be exploited to achieve some interesting and useful separations.

Donnan dialysis can be used for changing compositions of process or analytical solutions, pollution control, and even deionization of a process stream. The deionization process, called 'neutralization dialysis',

combines Donnan dialysis through both cation-exchange and anion-exchange membranes in one apparatus with H^+ and OH^- ions exchanging for the cation and anion of a salt.

In the discussions that follow, the fundamental principles of Donnan dialysis will be presented, and some of its applications and capabilities will be described. The type of equipment and membrane arrangements appropriate for both Donnan dialysis and neutralization dialysis will be presented.

Background

The Donnan dialysis process is named after F. G. Donnan who in 1924 described the equilibrium that resulted when a semipermeable membrane separated two solutions of electrolytes, NaA on one side and KA on the other. The membrane he used was prepared by filling the pores of parchment paper with a gel of copper ferrocyanide, and he used ferrocyanide as the common anion A of the two salts. When the initial volumes and concentrations of the two salt solutions were the same, counterdiffusion of equal amounts of Na^+ and K^+ through the membrane led to an equilibrium condition where the two solutions had equal concentrations of NaA and KA. But when

Introduction

Donnan dialysis is a separation process that utilizes counterdiffusion of two or more ions through an ion-exchange membrane to achieve a separation. It can also be viewed as a continuous deionization process. For example, water softening can be done with a cation-exchange membrane. Hard water flows on one side of the membrane, and NaCl brine flows on the other side. Na^+ ions from the brine diffuse across the membrane and cause the Ca^{2+} and Mg^{2+} ions to diffuse in the opposite direction. Donnan dialysis is usually performed as a continuous, countercurrent process so that a substantial portion of a cation from a dilute solution could be concentrated into a small volume. Differences in the volumes and concentrations of the two solutions can be exploited to achieve some interesting and useful separations.

Donnan dialysis can be used for changing compositions of process or analytical solutions, pollution control, and even deionization of a process stream. The deionization process, called ‘neutralization dialysis’,

combines Donnan dialysis through both cation-exchange and anion-exchange membranes in one apparatus with H^+ and OH^- ions exchanging for the cation and anion of a salt.

In the discussions that follow, the fundamental principles of Donnan dialysis will be presented, and some of its applications and capabilities will be described. The type of equipment and membrane arrangements appropriate for both Donnan dialysis and neutralization dialysis will be presented.

Background

The Donnan dialysis process is named after F. G. Donnan who in 1924 described the equilibrium that resulted when a semipermeable membrane separated two solutions of electrolytes, NaA on one side and KA on the other. The membrane he used was prepared by filling the pores of parchment paper with a gel of copper ferrocyanide, and he used ferrocyanide as the common anion A of the two salts. When the initial volumes and concentrations of the two salt solutions were the same, counterdiffusion of equal amounts of Na^+ and K^+ through the membrane led to an equilibrium condition where the two solutions had equal concentrations of NaA and KA. But when

initial concentrations were different, counterdiffusion of equal amounts of Na^+ and K^+ through the membrane produced solutions with equal ratios of Na^+/K^+ on both sides of the membrane at equilibrium. This relationship of concentrations of the ions in the solutions on opposite sides of the membrane is called the 'Donnan equilibrium'.

Before proceeding with the theory, it is useful to define some terms that are often used in discussions of modern polymeric ion-exchange membranes. First, an 'ion-exchange membrane' is a plastic film with fixed ionically charged groups dispersed more or less uniformly within the film. Associated with the fixed charges are mobile charges of opposite sign called 'counterions'. The counterions are free to exchange with other counterions in the adjacent solutions. When the membrane has fixed negative charges, e.g., sulfonic acid groups, it is called a 'cation-exchange membrane', and the counterions are cations. In the external solutions, mobile anions are associated with the cations, but in the membrane the charge balance is satisfied by the fixed negative charges. Therefore, anions tend to be excluded from the interior of the cation-exchange membrane. The ions with the same charge as the fixed charge in the membrane are called 'co-ions'.

Theory

The Donnan equilibrium relationship is derived from thermodynamics. Under conditions of equilibrium the chemical potential μ_i of any dissolved species i is the same in every phase present:

$$\mu_i = \mu_i^\circ + RT \ln a_i \quad [1]$$

Here, μ_i° is the chemical potential of species i in the standard state, R is the gas law constant, T is the absolute temperature, and a_i is the activity of the particular chemical species i being considered. However, electrical potentials must also be considered when the chemical species are ionic, so the electrochemical potential η_i must be used to describe the equilibrium:

$$\eta_i = \mu_i^\circ + RT \ln a_i + z_i F \theta \quad [2]$$

where z_i is the ionic charge, F is Faraday's constant, and θ is the electrical potential. When the two liquids, phase 1 and phase 2, are at equilibrium with the membrane, there is also equilibrium between the two liquid phases, and the electrochemical potential of any mobile species i in the two phases can be equated.

$$\eta_{i1} = \eta_{i2}, \text{ or } RT \ln a_{i1} + z_i F \theta_1 = RT \ln a_{i2} + z_i F \theta_2 \quad [3]$$

It should be noted that the μ_i° terms cancel because the same standard state exists in both liquid phases. But the co-ions are not free to move through the membrane that separates the two liquid phases, so there is no opportunity for their concentrations to change. Whenever salt concentrations on opposite sides of the membrane differ, there will be a potential difference across the membrane caused by the concentration difference. This potential difference, called the 'Donnan potential', E_{Donn} , is described by rearrangement of eqn [3]:

$$\begin{aligned} E_{\text{Donn}} &= \theta_2 - \theta_1 = RT/z_i F (\ln a_{i1} - \ln a_{i2}) \\ &= RT/F \ln(a_{i1}/a_{i2})^{1/z_i} \end{aligned} \quad [4]$$

Since the Donnan potential acts on all mobile ionic species, the value of $(a_{i1}/a_{i2})^{1/z_i}$ is the same for all of the counterions in the system. In other words, the concentration difference of the co-ions causes an electrical potential that acts on the counterions.

As Donnan pointed out in his seminal description of the theory, a precise treatment of the equilibria would require the use of activities rather than concentrations of ions in the solutions. But the use of molar concentrations greatly simplifies the presentation of the theory, so that is the approach taken here. For the experiment described by Donnan where $z_i = +1$ for both Na^+ and K^+ ions, the equilibrium written with concentrations would be:

$$\begin{aligned} [\text{Na}^+]_1/[\text{Na}^+]_2 &= [\text{K}^+]_1/[\text{K}^+]_2 \text{ or } [\text{Na}^+]_1/[\text{K}^+]_1 \\ &= [\text{Na}^+]_2/[\text{K}^+]_2 \end{aligned} \quad [5]$$

Figure 1 illustrates the flow of ions in the approach to Donnan equilibrium. Two dilute salt solutions NaCl and KCl are separated a cation-exchange membrane, labelled C, which is permeable to the cations Na^+ and K^+ but impermeable to the common anion Cl^- . The concentration difference of Na^+ ions across the membrane provides a driving force for their diffusion through the membrane. There is no net flow of electric current through the membrane, so any net transfer of Na^+ to the right must be balanced by transfer of an equivalent amount of K^+ to the left. Those diffusive processes will occur until an equilibrium is established.

The equilibrium concentrations can be expressed in terms of the initial molar concentrations c_1 of NaCl on the left and c_2 of KCl on the right, x moles transported through the membrane (still the same for both cations) and the volumes V_1 and V_2 of the

Figure 1 Donnan potential forces K^+ ions to higher concentration.

solutions, expressed in litres:

$$(c_1 - x/V_1)/(x/V_1) = (x/V_2)/(c_2 - x/V_2) \quad [6]$$

Solving this equation for x yields:

$$x = c_1 c_2 / (c_1/V_2 + c_2/V_1) \quad [7]$$

Donnan dialysis is particularly effective for recovery or removal of multivalent ions. The Donnan equilibrium for a divalent Ca^{2+} ion and a univalent K^+ is described by the equation:

$$([Ca^{2+}]_1/[Ca^{2+}]_2)^{1/2} = [K^+]_1/[K^+]_2 \quad [8]$$

For maintenance of electroneutrality in the system, the transport of x moles of Ca^{2+} ions through the membrane requires the transport of $2x$ moles of K^+ ions in the opposite direction. Thus the equilibrium is described by:

$$[(c_1 - x/V_1)/(x/V_1)]^{1/2} = (2x/V_2)/(c_2 - 2x/V_2) \quad [9]$$

For $V_1 = 10$, $V_2 = 1$ and initial concentrations of $c_1 = 0.01$ and $c_2 = 1$, the value of $x = 0.095$ is calculated by eqn [9], which means that more than 95% of the calcium would be driven through the membrane. The effect of valence is even more dramatic

when the c_1/c_2 ratio is much lower than the value used in this example.

Comparison of Donnan Dialysis with Conventional Ion Exchange

In many respects Donnan dialysis can be viewed as a continuous ion-exchange process. For instance, both processes can be used for the softening of water. In conventional ion-exchange softening, the ion-exchange resin beads are initially in the Na^+ form. When hard water flows through a column of the Na^+ form resin beads, Ca^{2+} ions in the water exchange with Na^+ ions on the resin. When the supply of Na^+ ions on the resin approaches exhaustion, the flow of hard water is stopped, the resins are regenerated by passing $NaCl$ brine through the column, and then the cycle is repeated. In contrast, water softening with Donnan dialysis is a continuous process. The Na^+ ions for regeneration are always available in the solution on one side of the membrane, and the Ca^{2+} ions are continuously removed from the feed stream. Both processes are effective for water softening. Donnan dialysis works best in a situation where a continuous flow is expected. Softening with a bed of resin beads can easily accommodate variable flow rates or even on/off operation. Since water softening is most often done in situations where flow rates fluctuate widely, the use of resin beads rather than membranes is the accepted practice.

If a particular exchange of ions can be accomplished by the cyclic process with ion-exchange resin beads or the continuous process with ion-exchange membranes, what factors might influence the selection of the membrane process over the conventional process? Because the membrane process is continuous, it operates at steady-state conditions everywhere in the dialyser. In cases where acid or base is used to drive the process, conditions of pH extremes can be avoided more easily with Donnan dialysis than with conventional ion exchange. Compared to membranes, ion-exchange beads offers a large surface area in a small volume, so the rates of mass transfer are faster with beads. But that large surface area can be a problem if components of the solution are subject to denaturation at surfaces where pH extremes exist. Donnan dialysis can be a much gentler process.

A major limitation to Donnan dialysis is that, like ion exchange, there is a need to add chemicals to recover or remove chemicals. Essentially the stripper solution in Donnan dialysis serves the same function as the regenerant solution in ion exchange. Donnan dialysis has the added limitation that osmotic water transport makes the recovered electrolyte more dilute

than it would be in the spent regenerant of an ion-exchange process. However, Donnan dialysis has the advantages that it is continuous and does not require the rinse step after regeneration. If the application is one in which the stripper solution is already available and needs to have the transported ion in it, then the Donnan dialysis can be an advantageous process.

Neutralization Dialysis

Anion- and cation-exchange membranes can be combined into a single dialyser where both acid and base drive the transport of the cation and anion of a salt as illustrated in **Figure 2**. Since the hydrogen and hydroxyl ions that drive the transport are neutralized in the feed solution, the driving force for desalting can be maintained until almost all of the acid and base are consumed. Neutralization dialysis has been used effectively for desalination of aqueous solutions of organic compounds. Research has demonstrated that the flux of salt ions increases with acid and base concentration up to about 0.1 M. Above those levels there was little benefit in raising the acid and base concentrations.

It should be noted from Figure 2 that the membrane arrangement in neutralization dialysis is different from that in electrodialysis. Here there are four membranes in a repeating sequence, two anion-exchange membranes and then two cation-exchange

membranes. It is a fortunate circumstance in neutralization dialysis that the acid only contacts cation-exchange membranes, because anion-exchange membranes are notoriously leaky to acids. Likewise, the two anion-exchange membranes that bound the base compartments resist leakage of base.

Neutralization dialysis competes with deionization with mixed bed ion-exchange resins which has lower capital cost. But neutralization dialysis has the advantage of being a continuous process that can be controlled by the flow rates and concentrations of the acid and base. Moreover, the feed solution is not exposed to such severe pH extremes as it would be in deionization with ion-exchange resins.

Membranes for Donnan Dialysis

Many ion-exchange membranes are manufactured for electro dialysis, and most of them would be potentially useful for Donnan dialysis. In addition, the Nafion[®] fluoropolymer cation-exchange membranes made by DuPont are uniquely suited to Donnan dialysis because of their ability to withstand severe thermal and chemical attack. Fluoropolymer membranes have been used to recover chromic acid, a strong oxidizing agent that attacks hydrocarbon-based membranes. Nafion[®] has been made as small tubules and fabricated into shell-and-tube dialysers.

The preparation of hollow fibres for use in analytical devices was reported in 1981. Low-density polyethylene was extruded into 300 μM i.d., 380 μM o.d. hollow fibres that were sulfonated with 10% chlorosulfonic acid in methylene chloride. A bundle of eight hollow fibres was inserted into a coiled tube and sealed with silicone rubber caulk.

Although many types of ion-exchange membranes have been used for Donnan dialysis, there seem to be no published studies comparing the performance of commercial membranes for Donnan dialysis or establishing criteria for desirable membranes. One would expect diffusional transport properties of the membranes to parallel those of electrodialysis. In Donnan dialysis, membranes with low electrical resistance would be expected to have low resistance to ion diffusion, and those with low electroosmotic water transport would be expected to have low osmotic water transport. Of course the membranes should be stable at the anticipated operating temperatures of the process and resist chemical attack by solution components. Experimental studies have established that, under typical hydrodynamic conditions, the major resistance to transport is in the boundary layer of the dilute solution rather than in the membrane; therefore, even some of the thicker commercial ion-exchange membranes could be candidates for use in Donnan dialysis.

Figure 2 Neutralization dialysis for desalination. C = cation; A = anion.

Japanese researchers have made cation exchange membranes, specifically selective to the transport of uranyl ions, by forming a copolymer of 2,3-epithiopropyl methacrylate and 2-acrylamide-2-methylpropanesulfonic acid. They observed that the proportions of the monomers had a great effect on the ability of the membranes to transport uranyl ions. High transport was achieved when the 2-acrylamide-2-methylpropanesulfonic acid content was at least 34%, but very low transport occurred when that monomer comprised less than 21% of the membrane. By contrast, they found that the Selemion DLE membrane did not transport the uranyl ions under the same experimental conditions. The same researchers also made anion-exchange membranes of 2,3-epithiopropyl methacrylate-dodecyl methacrylate-methylacrylamide propyltrimethylammonium chloride terpolymer that selectively transported ferric oxalate complex anions from acidic ferric sulfate solution to a receiving solution containing sodium oxalate. These studies suggest that the development of ion-specific membranes could lead to selective separations by Donnan dialysis that cannot be economically achieved by other methods.

The amount of membrane area required for a particular Donnan dialysis application depends on the mass transfer rates that can be achieved. However, the user should be cautious about relying upon mass transfer data obtained in stirred cells to design industrial systems, because the high shear rates obtained by stirring might not be achieved in a commercial dialyser. Results reported for Donnan dialysis of uranyl ions in a countercurrent dialyzer should offer realistic mass transfer coefficients for design purposes. AM-Fion C-103 cation-exchange membranes separated solutions of 0.01 M $\text{UO}_2(\text{NO}_3)_2$ and 2 M HNO_3 . The solution compartments between the membranes were formed with 0.38-mm-thick woven screens of stainless steel. Uranyl ion fluxes were about $9 \times 10^{-10} \text{ mol cm}^{-2} \text{ s}^{-1}$. The treatment rate was about $3 \text{ L h}^{-1} \text{ m}^{-2}$, and 96% of the $\text{UO}_2(\text{NO}_3)_2$ was recovered.

Apparatus

The equipment used for Donnan dialysis is similar to that used for dialysis and diffusion dialysis. Membrane shapes include sheets, tubes, and hollow fibres. Sheet membranes have been fabricated into spiral-wound devices, but the dominant configuration for flat membranes is the plate-and-frame arrangement used in electrodialysis. Thus any supplier of electrodialysis equipment is a potential supplier of stacks for Donnan dialysis. Since the major resistance to transport usually lies in the boundary layer of the

dilute solution, equipment designers strive to achieve high shear in the feed solution. There is a major advantage to countercurrent flow of the feed and stripper solutions, because that configuration leads to maximum driving forces and maximum total transfer of the desired ions.

In a commercial dialyser, the simultaneous achievement of both high shear and countercurrent flow is difficult. High shear can be achieved by rapid stirring or by high flow rates, but the benefits of countercurrent flow can only be achieved if the residence time in the device is sufficient for a large fraction of the desired ion to be transferred through the membrane. As discussed below, studies of the effects of solution velocity on mass transfer rates show correlation with V^n where the exponent n is always less than unity. This means that increasing the solution velocity through a dialyser of a given length always results in a smaller fraction of the solute being transferred through the membrane. Therefore, an increase in solution velocity requires an increase in path length to achieve the same fraction of transfer. (This V^n relationship also applies to dialysis, diffusion dialysis, and electrodialysis.)

Process Design and Control

Most often the objective of Donnan dialysis is to both recover a target ionic species from a feed solution and raise its concentration. An increase in the concentration is achieved by the use of a small volume of a stripper solution with a diffusing ionic species that is higher in concentration than that of the target ionic species in the feed. A strip solution of about 1 M might be used with a typical 0.001 M feed solution. One might expect that a more concentrated strip solution would recover the target ionic species at a higher concentration, but stripper concentrations higher than 1 M do not seem to be beneficial. More concentrated strip solutions lead to osmotic dehydration of the gel structure of the membrane which reduces membrane permeability. Moreover, co-ion transport due to reduced Donnan exclusion at the higher concentrations allows loss of solutes from the receiving solution across the membrane, and osmotic transport of water through the membrane dilutes the strip solution.

The effects of hydrodynamics on mass transfer rates in Donnan dialysis have been studied by several researchers who correlated the data using the standard equation $\text{Sh} = k\text{Sc}^m\text{Re}^n$. The Sherwood number $\text{Sh} = KD/h$, Schmidt number $\text{Sc} = \mu/\rho D$, and Reynolds number $\text{Re} = \rho hV/\mu$ are dimensionless parameters where K is the mass transfer coefficient, D is the diffusivity of the diffusing ionic species, h is

Table 1 Dimensionless parameters for correlation of mass transfer rates in Donnan dialysis through Nafion®

Cation	Strip acid	<i>k</i>	<i>m</i>	<i>n</i>
Cu ²⁺	H ₂ SO ₄	0.48	0.33	0.28
Ni ²⁺	H ₂ SO ₄	0.166	0.33	0.475
Na ⁺ , K ⁺	HNO ₃	0.201	0.4	0.62

the characteristic thickness or diameter of the conduit, μ is the solution viscosity, ρ is specific gravity, and V is solution velocity. The coefficient k , and the exponents m and n are used to correlate the data. The results of three studies are shown in **Table 1**, and some comments about the experiments follow.

Studies with CuSO₄ and NiSO₄ were done with the feed flowing inside a fluoropolymer membrane tube a few millimetres in diameter and with H₂SO₄ stripper flowing outside the tube. The correlation parameters apply to $Re < 1000$. The following observations were made in the studies with CuSO₄ and NiSO₄. Increasing the stripper concentration from 1 to 5 M did not improve mass transfer. Increasing the solution velocity of the stripper solution produced minor increases in mass transfer. The mass transfer rate was proportional to the metal ion concentration in the feed for concentrations below 2000 mg L⁻¹ and $Re < 1000$. Studies of NaNO₃ and KNO₃ feeds with HNO₃ stripping were done with a flat sheet fluoropolymer membrane in a stirred cell with $15 > Re > 400$.

Since the flow rates in Donnan dialysis are normally rather low, one must be concerned with convective flow in the dialyser caused by density changes in the solutions as their compositions change. The use of excessively high acid concentrations in the stripper exacerbates the problem of changing densities. Osmotic transport of water into the acid stripper solution at the top of the solution compartment can cause substantial dilution of the acid, and the resulting density decrease allows the denser incoming stripper to stream downward through the diluted acid. The problem can be alleviated by mild pulsation of the solution at the top of the stripper side to improve mixing.

Applications

Although many industrial applications have been demonstrated in the laboratory and at the pilot scale, there appear to have been few industrial-scale applications of Donnan dialysis. Industrial applications have been mainly in recovering heavy metals from rinse waters of metal-finishing operations. One of the few descriptions of an industrial installation reports results of an experimental evaluation of a DuPont-made Nafion® hollow-fibre dialyser for metal recov-

ery from rinse water in a Watts nickel electroplating process with 1 M H₂SO₄ as the stripper. With typical feed concentrations of up to 1 g L⁻¹, Ni²⁺ fluxes exceeded 20 g h⁻¹ m⁻² and the recovered Ni concentration exceeded 30 g L⁻¹.

An early application of Donnan dialysis with polymeric ion-exchange membranes was described in 1967. Multiple AMFion C-103C cation-exchange membranes were assembled in a plate-and-frame dialyser with solution compartments arranged so that the feed and strip streams could flow in a pattern that was countercurrent overall. This apparatus was used to recover UO₂(NO₃)₂ from a 0.01 M feed to a final concentration of 0.28 M with 2 M HNO₃ as the stripper and to 0.46 M with 2 M H₂SO₄ as the stripper. He also used a Donnan dialyser with AMFion A-104B anion-exchange membranes to remove acid from the UO₂(NO₃)₂ feed to improve the driving force for cation transport. Complexing agents, EDTA and DPTA, were used as strippers to separate Ag⁺ and Cu²⁺ ions. The Cu²⁺ ions formed such strong complexes that the free Cu²⁺ ion concentration in the stripper was low enough to maintain a driving force until virtually all of the Cu²⁺ ions were transported across the membrane.

The use of Donnan dialysis for water softening was reported in 1970. The process is illustrated in **Figure 3**. A brine of NaCl and hard feed water flow countercurrent. The diffusion of Na⁺ ions from the

Figure 3 Donnan dialysis removes Mg²⁺ ions from hard water. C = cation.

brine causes a driving force for transport of Mg^{2+} ions from the feed into the brine. Countercurrent operation allows the large driving force to be maintained over the length of the membrane.

A hollow-fibre device has been used as a suppressor for ion chromatography. Compared to an ion-exchange column that is normally used to suppress conductance in the eluant, Donnan dialysis allowed more control over the conductivity and eliminated the need to regenerate the resins. Moreover, the resolution was improved by the use of Donnan dialysis.

The use of neutralization dialysis for desalination of cheese whey has been described.

Conclusion

Donnan dialysis can be used in many applications where ion-exchange beads are currently applied. The process might find a niche in water softening in a capacity range between that of home water softeners and the large-scale lime-soda softeners. Capital costs are higher for membranes than for resin beads, but the use of membranes offers the advantages of steady-state operation without the need for rinse-down, which produces large volumes of water that must be discarded. The capital cost of small-scale Donnan dialysis could be reduced by the availability of more ion-exchange membranes in hollow-fibre form that could be assembled into compact modules.

Electrodialysis

H. Strathmann, University of Twente, The Netherlands

Copyright © 2000 Academic Press

Electrodialysis is a process in which ion exchange membranes in combination with an electrical potential difference are used to remove ionic species from an aqueous solution. The large scale industrial utilization of the process began about 30 years ago with the development of highly selective ion exchange membranes of low electric resistance arranged in a multicell stack.

Until the mid 1970s electrodialysis stacks were operated in a unidirectional mode, that is, the polar-

ity of the electrodes was fixed. A significant step towards the efficient application of electrodialysis was the introduction of a new mode of operation referred to as electrodialysis reversal. In this operating mode the flow streams and the polarity in an electrodialysis stack are periodically reversed, which reduces membrane fouling and scaling. Costly and time-consuming membrane cleaning procedures are then unnecessary.

The main application of electrodialysis is the desalination of brackish water for domestic and industrial use. In Japan electrodialysis is also used on a large scale to concentrate sodium chloride from sea water for the production of table salt. More recently

brine causes a driving force for transport of Mg^{2+} ions from the feed into the brine. Countercurrent operation allows the large driving force to be maintained over the length of the membrane.

A hollow-fibre device has been used as a suppressor for ion chromatography. Compared to an ion-exchange column that is normally used to suppress conductance in the eluant, Donnan dialysis allowed more control over the conductivity and eliminated the need to regenerate the resins. Moreover, the resolution was improved by the use of Donnan dialysis.

The use of neutralization dialysis for desalination of cheese whey has been described.

Conclusion

Donnan dialysis can be used in many applications where ion-exchange beads are currently applied. The process might find a niche in water softening in a capacity range between that of home water softeners and the large-scale lime-soda softeners. Capital costs are higher for membranes than for resin beads, but the use of membranes offers the advantages of steady-state operation without the need for rinse-down, which produces large volumes of water that must be discarded. The capital cost of small-scale Donnan dialysis could be reduced by the availability of more ion-exchange membranes in hollow-fibre form that could be assembled into compact modules.

Electrodialysis is a process in which ion exchange membranes in combination with an electrical potential difference are used to remove ionic species from an aqueous solution. The large scale industrial utilization of the process began about 30 years ago with the development of highly selective ion exchange membranes of low electric resistance arranged in a multicell stack.

Until the mid 1970s electrodialysis stacks were operated in a unidirectional mode, that is, the polar-

ity of the electrodes was fixed. A significant step towards the efficient application of electrodialysis was the introduction of a new mode of operation referred to as electrodialysis reversal. In this operating mode the flow streams and the polarity in an electrodialysis stack are periodically reversed, which reduces membrane fouling and scaling. Costly and time-consuming membrane cleaning procedures are then unnecessary.

The main application of electrodialysis is the desalination of brackish water for domestic and industrial use. In Japan electrodialysis is also used on a large scale to concentrate sodium chloride from sea water for the production of table salt. More recently

Figure 1 Schematic diagram illustrating the principle of electrodialysis.

utilization of electrodialysis in the food and chemical industry and to treat certain industrial effluent streams has become important.

The Principle of Electrodialysis

The principle of electrodialysis is illustrated in **Figure 1**. A typical electrodialysis cell arrangement consists of a series of anion and cation exchange membranes arranged in an alternating pattern between an anode and a cathode to form individual cells. If an electrolyte solution is passed through these cells and an electrical potential is established between the electrodes, the positively charged cations migrate towards the cathode and the negatively charged anions towards the anode. The positively charged cations can easily permeate the negatively charged cation exchange membrane but are retained by the positively charged anion exchange membrane. Likewise, negatively charged anions permeate the anion exchange membrane but are retained by the cation exchange membrane. The overall result is an increase in the ion concentration in alternate compartments, while the other compartments simultaneously become depleted. The depleted solution is referred to as diluate and the concentrated solution as brine or concentrate. The driving force for the ion transport in the electrodialysis process is the applied electrical potential. The total space occupied by the diluate and the concentrated solutions and the contiguous anion and cation exchange membranes make up a cell pair. The cell pair is the repeating unit in an electrodialysis stack.

The Ion Exchange Membranes

Ion exchange membranes are the key components in electrodialysis. They consist of highly swollen gel-type polymer structures carrying fixed positive or negative charges. Polymer structures carrying negatively charged groups are referred to as cation

exchange membranes, while those carrying positively charged groups are referred to as anion exchange membranes.

In a cation exchange membrane, the fixed negative charges are in electrical equilibrium with mobile cations in the interstices of the polymer. **Figure 2** shows a cation exchange membrane with fixed anions and mobile cations; the latter are referred to as counter ions. The mobile anions, called co-ions, are more or less completely excluded from the polymer matrix because their electrical charge is identical to that of the fixed ions. Because of the exclusion of the co-ions, cation exchange membranes are preferentially permeable for cations. Anion exchange membranes which carry positive fixed charges and exclude cations are preferentially permeable to anions. The extent to which co-ions are excluded from an ion exchange membrane depends on the membrane as well as on the solution properties.

The most desirable properties for ion exchange membranes are:

- High permselectivity – the membrane should be permeable to counter-ions only
- Low electrical resistance – the membrane should have high counter ion permeability
- Good mechanical and form stability – the membrane should be mechanically strong and should have a low degree of swelling in diluate solutions
- High chemical stability – the membrane should be stable over the entire pH range and in the presence of oxidizing agents and organic solvents.

The properties of ion exchange membranes are determined by the base polymer and the type and concentration of the fixed charges. The base polymer determines the mechanical, chemical and thermal

Figure 2 Schematic drawing illustrating the structure of a cation exchange membrane.

stability of the membrane. The type and concentration of the fixed ions determine the permselectivity and the electrical resistance. The moieties often used as fixed charges are $-\text{SO}_3^-$ and $-\text{COO}^-$ groups in cation exchange membranes and $-\text{R}_3\text{N}^+$ and $-\text{R}_2\text{NH}^+$ groups in anion exchange membranes. The sulfonic acid group $-\text{SO}_3^-$ is completely dissociated over the entire pH range, while the carboxylic acid group $-\text{COO}^-$ is virtually undissociated in the pH range < 3 . The quaternary ammonium group $-\text{R}_3\text{N}^+$ again is completely dissociated over the entire pH range, while the tertiary ammonium group $-\text{R}_2\text{NH}^+$ is only weakly dissociated. Accordingly, ion exchange membranes are referred to as weakly or strongly acidic or basic in character depending on the charged groups they contain.

Mass Transfer in Electrodialysis

Mass transfer in electrolyte solutions is determined by the driving forces acting on the individual ions of the solution and by the friction of the ions with other components in the solution. The driving forces can be expressed by gradients in the electrochemical potential of individual components. The friction that has to be overcome by the driving force can be expressed by the ion mobility or diffusivity.

To describe the mass transport in a system, thermodynamic and kinetic parameters must be mathematically related. Several relations are described in the literature. The one most frequently used is the Nernst-Planck equation which describes transport of ions under isobaric and isothermal conditions in an ion exchange membrane as follows:

$$J_i = m_i C_i \frac{d\eta_i}{dz} = m_i C_i \left(z_i F \frac{d\varphi}{dz} + \frac{d\mu_i}{dz} \right) \\ = m_i C_i \left(z_i F \frac{d\varphi}{dz} + RT \frac{d \ln a_i}{dz} \right) \quad [1]$$

For the definition of symbols in this and all other equations, see Table 1. J_i is the flux in the direction perpendicular to the membrane surface and z refers to the number of charges carried by an ion and indicates whether these charges are positive or negative.

A boundary condition for describing the mass transport in electrolyte solutions is the electroneutrality requirement which postulates that on a macroscopic scale there is no excess in positive or negative charges. Thus:

$$\sum_i z_i C_i = 0 \quad (i = 1, 2, 3 \dots n) \quad [2]$$

The concentration of individual ions is related to that of the salt by the stoichiometric coefficient ν which determines into how many ions a salt will dissociate in the solution. Thus:

$$C_i = \nu_i C_s \quad [3]$$

Another assumption in electrodialysis is that electrical charges are transported exclusively by ions. Thus:

$$I = \sum_i z_i F J_i \quad [4]$$

Here J_i is the flux of the individual ions and I is the total electrical current.

Transport and Transference Numbers

The transport number T_i and the transference number t_i of an ion i are given by:

$$T_i = \frac{z_i J_i}{\sum_i z_i J_i} \quad \text{and} \quad t_i = \frac{T_i}{z_i} = \frac{J_i}{\sum_i z_i J_i} \quad [5]$$

Here T_i indicates the fraction of the total current carried by the ion i , and t_i determines the number of moles of the ion i transported per mole of electrons, i.e. per Faraday.

The transference number is directly related to the ion concentration and their mobility and its sum is 1. Thus:

$$t_i = \frac{C_i m_i}{\sum_i z_i C_i m_i} \quad \text{and} \quad \sum_i t_i = 1 \quad [6]$$

The transference numbers of different salt ions in solution are not very different. In an ion exchange membrane, however, there are the fixed ions of the membrane in addition to the mobile ions of the electrolyte. The fixed ions do not contribute to the transport of electrical charges. Their transference number is therefore 0. Furthermore, the concentration of the counterions is much lower than that of the co-ions. Their concentration in the membrane determines the permselectivity of a membrane.

Membrane Permselectivity

The permselectivity of cation and anion exchange membranes is defined by:

$$\psi^{\text{mc}} = \frac{t_c^{\text{mc}} - t_c}{t_a} \quad \text{and} \quad \psi^{\text{ma}} = \frac{t_a^{\text{ma}} - t_a}{t_c} \quad [7]$$

Table 1 Definition of symbols used in mathematical equations

Symbol	Definition
η	Electrochemical potential
μ	Chemical potential
φ	Electrical potential
ν	Stoichiometric coefficient which determines into how many ions a salt will dissociate in the solution
ψ	Permselectivity of a membrane
ξ	Current utilization
Δ	Thickness of a cell
ρ	Resistance of ion exchange membranes
$\Delta\varphi$	Potential difference between solutions separated by a membrane assuming electrochemical equilibrium
ΔC	Difference in salinity of feed and product water
φ_{Don}	Donnan potential
ΔG	Energy required for production of the dilute
γ_{\pm}^m	Average activity coefficients of salt in the membrane
Δn_s	Amount of salt in moles transferred from a feed to a concentrate solution
Δp	Hydrodynamic pressure loss through the stack
Λ_s	Equivalent conductivity
γ_{\pm}^s	Average activity coefficients of salt in the electrolyte solution
Δz	Thickness of the boundary layer
a	Activity
A	Effective area
A_{min}	Minimum membrane area required for a certain plant capacity
ΔC	Concentration differences between feed and diluate
C_{co}^m	Co-ion concentration in the membrane
C_i^m	Concentration fixed ions in the membrane
C_{co}^s	Co-ion concentration in the electrolyte solution
D	Diffusion coefficient
dz	Directional coordinate perpendicular to the membrane surface
E_{des}	Energy required for desalination
E_p	Pumping energy
F	Faraday constant
I	Total electrical current
i	Current density
i_{lim}	Limiting current density
J_i	Flux of component i (individual ions)
k	Constant referring to efficiency of pumps
m	Mobility of ions in the membrane
n	Number of cell pairs in a stack
Q	Volumetric flow of the product
R	Gas constant
R	Electric resistance
T	Temperature
t	Transference number
t	Time
T_i	Transport number of component i (ions)
u	Linear flow velocity of solution in electrodialysis cells
U	Voltage drop across the electrodialysis stack
V	Volume
z	Electrochemical valence

Superscripts

' and ''	Two phases separated by the membrane
b	Boundary layer
ba	Concentrate bulk solution
bc	Concentrate bulk solution

Table 1 Continued

Symbol	Definition
bd	Diluate solution in the bulk
diff	Ion diffusion
l	Current leakage through the manifold
m	Membrane
ma	Anion membrane
mc	Cation membrane
md	Diluate solution at the membrane surface
mig	Ion migration
ms	Membrane selectivity
o	Feed
p	Product solution
s	Solution
sc	Concentrate solution
sd	Diluate concentration
se	Electrode rinse solution
sf	Feed solution
sp	Product solution
w	Water transport through the membranes

Subscripts

a	Anion
c	Cation
cou	Counterion
i	Ion
s	Salt
w	Water

The permselectivity of an ion exchange membrane relates the transport of electric charges by counterions to the total transport of electric charges through the membrane. An ideal permselective cation exchange membrane would transmit positively charged ions only, i.e. for $t_c^{\text{mc}} = 1$, $\psi^{\text{mc}} = 1$. The permselectivity approaches zero when the transference number within the membrane is identical to that in the electrolyte solution. For the anion exchange membrane the corresponding relationship holds.

Diffusion Potential, Donnan Equilibrium and Ion Exclusion

The diffusion potential can be derived by integration of eqn [1] and is given for a monovalent electrolyte when the ion activity is expressed by the salt concentration by:

$$\Delta\varphi = \varphi' - \varphi'' = \frac{RT}{F} \left(\frac{m_a - m_c}{m_a + m_c} \right) \ln \frac{C_s'}{C_s''} \quad [8]$$

An electrical potential difference is not only established between two solutions of different concentrations separated by a membrane but also between a membrane and the adjacent electrolyte solution if the ion concentration in the membrane is different from that in the adjacent solution,

which is generally the case with ion exchange membranes. This potential difference is referred to as the Donnan potential.

The Donnan potential cannot be measured directly. It can, however, be calculated from the electrochemical equilibrium of ions between the membrane and the adjacent solution. By introducing the proper relations for the electrochemical potential, the Donnan potential – the electrical potential difference between an ion exchange membrane and a solution of a monovalent salt – can be calculated to a first approximation by:

$$\Delta\phi_{\text{Don}} = \phi^m - \phi^s = \frac{RT}{F} \ln \frac{a_i^m}{a_i^s} \quad [9]$$

The numerical value of $\Delta\phi_{\text{Don}}$ is negative for the cation exchange membrane and positive for the anion exchange membrane in equilibrium with a dilute electrolyte solution.

The Donnan potential is also the basis for calculating the Donnan exclusion, which determines the co-ion concentration in a membrane. For a monovalent electrolyte, i.e. $z_i = 1$, and assuming a high fixed ion concentration in the membrane compared to the electrolyte concentration, the co-ion concentration in the membrane is given to a first approximation by:

$$C_{\text{co}}^m = \frac{C_{\text{co}}^s}{C_{\text{f}}^m} \left(\frac{\gamma_{\pm}^s}{\gamma_{\pm}^m} \right)^2 \quad [10]$$

Energy Requirements in Electrodialysis

The energy required in an electrodialysis process is the sum of two terms: firstly, the electrical energy needed to transfer the ionic components from a feed solution through the membranes into the concentrate solution, and secondly, the energy required to pump the solutions through the electrodialysis unit. Energy consumption due to electrode reactions can generally be neglected because of the large number of cell pairs usually stacked between the two electrodes.

Minimum Energy Required for Transfer of Ions from a Feed to a Concentrate Solution

In electrodialysis the minimum energy required for the transport of salt from a feed to a concentrate solution can be expressed by the Gibbs free energy of mixing. Taking into account the electrolyte concentrations in the feed, diluate and concentrate, the minimum desalting energy is given by:

imum desalting energy is given by:

$$\Delta G = zRT\Delta n_s \left[\frac{\ln \frac{C_s^{\text{sf}}}{C_s^{\text{sc}}}}{\frac{C_s^{\text{sf}}}{C_s^{\text{sc}}} - 1} - \frac{\ln \frac{C_s^{\text{sf}}}{C_s^{\text{sd}}}}{\frac{C_s^{\text{sf}}}{C_s^{\text{sd}}} - 1} \right] \quad [11]$$

Practical Energy Requirements in Electrodialysis

As discussed previously, the minimum energy required for desalting a given feed solution refers to a reversible process. In electrodialysis there are also irreversible energy losses and the total electric energy required for the transfer of ions from a feed solution to a concentrate, i.e. the actual energy used for desalination is much larger than the theoretical minimum value. This is given by:

$$E_{\text{des}} = UIt = RI^2t \quad [12]$$

The electric current required for the desalination of a feed solution is directly proportional to the concentration difference between the feed and the diluate solution. It is given by:

$$I = \frac{V^p |z_a| |z_c| \nu_s F (C_s^{\text{sf}} - C_s^{\text{sp}})}{\xi t} \quad [13]$$

The current utilization is the fraction of the total current passing through the electrodialysis stack that is used for the transfer of ions. It will be discussed in more detail later.

The electrical resistance of an electrodialysis stack is determined by the resistances of the membrane and diluate and concentrate solutions and is given to a first approximation by:

$$R = \frac{U}{I} = \frac{n}{A} \left[\frac{2\Delta}{\Lambda_s} \left(\frac{1}{C_s^{\text{sd}}} + \frac{1}{C_s^{\text{sc}}} \right) + \rho^{\text{ma}} + \rho^{\text{mc}} \right] \quad [14]$$

The electrical resistance of the solutions is inversely proportional to their salt concentrations, which are changing while passing through the stack from the feed to the product concentration. The concentration in the diluate cell is decreasing and that in the concentrate cell increasing. An electrical resistance of a stack can thus be calculated as a function of the cell thickness, i.e. the distance between two membranes. Generally, the resistances of the ion exchange membranes and the average resistance of the concentrate solution are much lower than the average resistance of the diluate and can therefore be neglected.

The electrical resistance of a stack can be calculated to a first approximation from the integral

average of the diluate concentration and is given by:

$$R = \frac{n}{A} \left[\frac{\Delta \ln \frac{C_s^{\text{sf}}}{C_s^{\text{sp}}}}{\Lambda_s(C_s^{\text{sf}} - C_s^{\text{sp}})} \right] \quad [15]$$

The superscripts sf and sp refer to the feed and the diluate at the cell outlet, which is the required product.

A combination of eqns [13] and [15] gives the energy required to remove a certain amount of salt from a feed solution. For the desalination of a monovalent salt, i.e. where z_a , z_c and ν_s are all unity, the electrical energy is given by:

$$E_{\text{des}} = \frac{n}{A} \frac{V^{\text{p}^2} F^2 (C_s^{\text{sf}} - C_s^{\text{sp}})}{\xi} \left[\frac{\Delta \ln \frac{C_s^{\text{sf}}}{C_s^{\text{sp}}}}{\Lambda_s} \right] \quad [16]$$

For a given plant capacity, salt solution and cell design, the equivalent conductivity and the number and area of cells are constant. Thus, the energy required for the desalination of a monovalent salt solution can be expressed to a first approximation by the constant factor k , by the current utilization and by the feed and the product concentration.

$$E_{\text{des}} = \frac{k}{\xi} (C_s^{\text{sf}} - C_s^{\text{sp}}) \log \frac{C_s^{\text{sf}}}{C_s^{\text{sp}}} \quad [17]$$

Pumping Energy Requirements

The operation of an electrodialysis unit requires one or more pumps to circulate the diluate, the concentrate and the electrode rinse solution through the stack. The energy required for pumping these solutions is determined by the volumes to be circulated and the pressure drop. It can be expressed by:

$$E_p = k(V\Delta p^{\text{sd}} + V^{\text{sc}}\Delta p^{\text{sc}} + V^{\text{se}}\Delta p^{\text{se}}) \quad [18]$$

Processes Affecting the Efficiency of Electrodialysis

In practical application electrodialysis is effected by concentration polarization and by incomplete current utilization. Both phenomena influence the efficiency of the process.

Current Utilization

Current utilization in an electrodialysis stack is impaired by incomplete membrane selectivity, parallel

current through the stack manifold and water transfer across the membranes due to osmosis and electroosmosis.

The ratio of the actual current needed for salt transport from a feed to a concentrate stream to that calculated theoretically is referred to as the current efficiency, which for one cell pair is given by:

$$\eta = \eta^{\text{ms}} \eta^{\text{w}} \eta^{\text{l}} \quad [19]$$

The efficiency term η^{ms} is a function of the membrane permselectivities. η^{w} is caused by convective flow due to the hydrostatic pressure difference between the diluate and concentrate cells, by transfer of water in the hydration shell of ions and by osmosis. η^{l} is determined by parallel current through the stack manifold.

The overall current utilization ξ can be defined as a function of the number of cell pairs, membrane selectivity, water transfer and manifold current flow. It is given by:

$$\xi = n(\psi^{\text{mc}} t_a + \psi^{\text{ma}} t_c) (1 - [t_w^{\text{mc}} + t_w^{\text{ma}}]) \times 0.018 (C_s^{\text{sc}} - C_s^{\text{sd}}) \eta^{\text{l}} \quad [20]$$

For relatively dilute solutions, $C_s < 0.1 \text{ mol L}^{-1}$, the efficiency loss due to water transfer is quite low. However, for higher feed solution salt concentrations the water transfer may affect the efficiency of electrodialysis quite significantly.

The current leakage through the manifold system can, in a well-designed stack, be neglected, i.e. $\eta^{\text{l}} \approx 1$.

Concentration Polarization and Limiting Current Density

Concentration polarization occurs in all mass separation processes and is the result of changes in mass transport properties at an interface. In electrodialysis, separation of ions is the result of differences in their transport numbers in solution and in the membranes. At the surface of an ion exchange membrane facing the diluate the concentration of counterions is reduced and at the surface facing the concentrate the concentration of counterions is increased because of the lower transport number of the counterions in the solution than that in the membrane. Because of the electroneutrality requirement, the co-ions in the boundary layers are transported in the opposite direction. Thus, salt concentration gradients are established in the boundary layers at membrane surfaces, which leads to an additional mass transport towards the membrane surface in the diluate and away from it in the concentrate solution. Due to turbulent mixing

Figure 3 Schematic drawing illustrating concentration profiles of a salt in the boundary layer on both sides of an ion exchange membrane and the fluxes of cations and anions in the boundary layer and the membrane surface. For abbreviations, see Table 1.

of the bulk solutions, the concentration gradients are limited to a relatively thin laminar boundary layer at the membrane surfaces, as indicated in **Figure 3**, which shows the salt concentration profiles in the solutions near the surface of an anion exchange membrane.

The concentration profiles at the membrane surface can be determined by a mass balance based on the so-called Nernst film model, which assumes static boundary layers at the membrane surfaces, where concentration and electrical potential gradients perpendicular to the membrane surfaces are the only driving forces for the mass transport. The bulk solution between the laminar boundary layer is well mixed and has a uniform concentration. It can be assumed that the transport of ions through an ion exchange membrane is the result of migration caused only by an electrical potential gradient, while in the solution ions are transported by both migration and diffusion. In a steady state the ion flux through the membrane is identical to that through the boundary layer. For a strictly permselective membrane it is given by:

$${}^m J_{\text{cou}}^{\text{mig}} = - {}^b J_{\text{cou}}^{\text{mig}} + {}^b J_{\text{cou}}^{\text{diff}} = t_{\text{cou}}^m \frac{i}{F} = t_{\text{cou}}^b \frac{i}{F} - D_s \frac{dC_s}{dz} \quad [21]$$

The current density can be obtained from eqn [21] by integration over the boundary layer. For the boundary layer at the membrane surfaces adjacent to the diluate the current density is:

$$i = - \frac{FD_s}{(t_{\text{cou}}^m - t_{\text{cou}}^b)} \frac{{}^b dC_s - {}^m dC_s}{\Delta z} \quad [22]$$

When the hydrodynamic flow conditions are kept constant the boundary layer thickness, Δz , will be constant and the current will reach a maximum value independent of the electrical potential gradient if the salt concentration at the membrane surface, ${}^m dC_s$, becomes 0. This maximum current is referred to as the limiting current density, i_{lim} , which is given by:

$$i_{\text{lim}} = - \frac{FD_s}{(t_{\text{cou}}^m - t_{\text{cou}}^b)} \frac{{}^b dC_s}{\Delta z} \quad [23]$$

Exceeding the limiting current density in practical applications of electrodialysis can affect the efficiency of the process severely by increasing the electrical resistance of the solution and by causing water splitting, which leads to changes in the pH values of the solutions, causing precipitation of metal hydroxides on the membrane surface.

Electrodialysis Process and Equipment Design

The performance of electrodialysis in practical applications is not only a function of membrane properties but is also determined by the membrane stack and the overall process design.

Electrodialysis Stack Design

Two different stack designs are used in large scale applications today. One is the so-called sheet flow and the other is the tortuous path flow design. A typical sheet flow electrodialysis stack is shown in

Figure 4 Exploded view of an electrodialysis stack arrangement, indicating the individual cells and the sheet flow-type spacer, also containing the manifolds for distribution of different flow streams.

Figure 4. The membranes are stacked between electrodes in such a way that the flow streams are kept separate. The gaskets that separate the membranes contain manifolds to distribute the process fluids to the different compartments. The supply ducts for the diluate and the concentrate are formed by matching holes in the gaskets, in the membranes, and in the electrode cells. To minimize the resistance of the aqueous solution, the distance between the membrane sheets is made as small as possible and is normally between 0.5 and 2 mm in industrial electrodialysis stacks. In an industrial electrodialysis system, 200–1000 cation and anion exchange membranes are installed in parallel to form an electrodialysis stack with 100–500 cell pairs. Spacers between the individual membrane sheets support the membranes and provide mixing of the flow streams.

A proper electrodialysis stack design provides the maximum effective membrane area per unit stack volume and ensures uniform flow distribution

through each compartment. The spacer screen should provide a maximum of mixing of the solutions at the membrane surfaces to reduce concentration polarization, but the pressure loss must be small.

Process Design and Modes of Operation

The efficiency of electrodialysis in a given application depends greatly on the process, design and mode of operation. Two different operating modes are currently used: the first is referred to as unidirectional electrodialysis and the second as electrodialysis reversal.

A flow diagram of a typical unidirectionally operated electrodialysis plant is shown in **Figure 5**. Feed solution pumped into the stack is converted to a diluate and a concentrate which are collected in storage tanks when the desired degree of concentration or depletion is achieved. To prevent the formation of free chlorine by anodic oxidation, the electrode cells are rinsed with a separate solution that

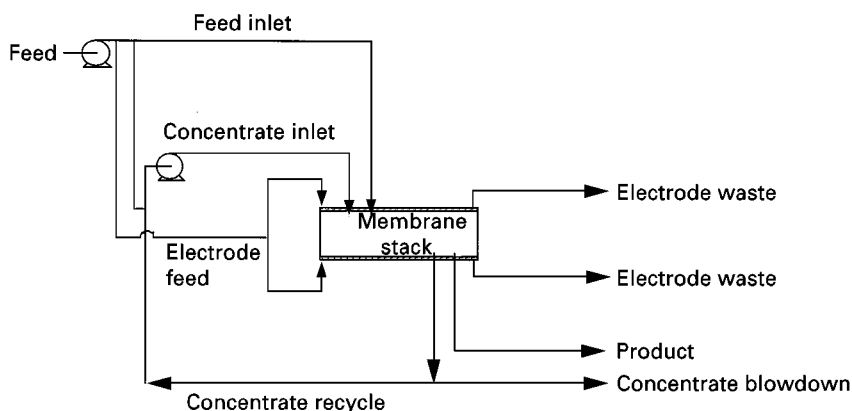

Figure 5 Flow scheme of the unidirectional electrodialysis operating mode.

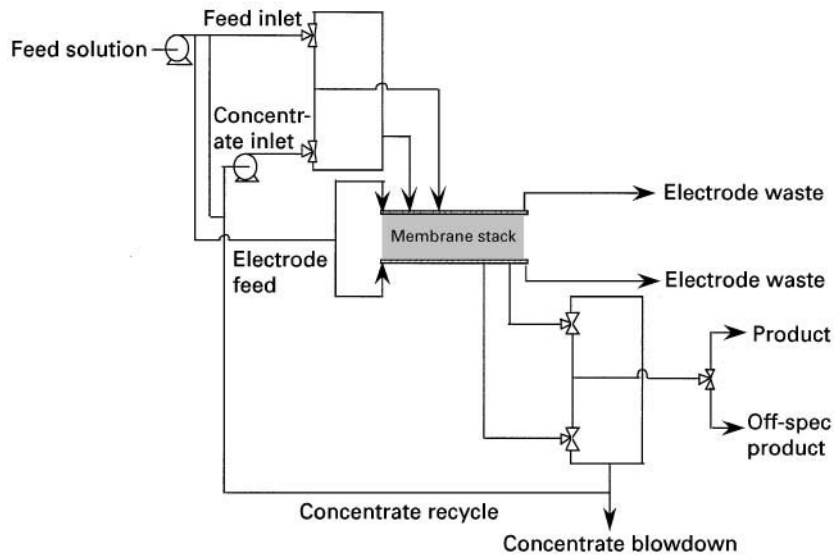

Figure 6 Flow scheme of the electrodialysis reversal operating mode.

does not contain chloride ions. Unidirectionally operated electrodialysis plants are rather sensitive to membrane fouling and scaling and often require careful feed solution pretreatment and stack-cleaning procedures.

Membrane fouling and scaling can be greatly reduced by operating in the electrodialysis reversal mode. In this operating mode, the polarity of the current is changed periodically every few minutes to a few hours. Simultaneously, the hydraulic flow streams are reversed, as shown in **Figure 6**. The advantage of the electrodialysis reversal operating mode is that precipitates that are formed in the concentrate cells are redissolved when the flow is reversed and these cells become the diluate cells. In the electrodialysis reversal operating mode there is a brief period when the concentration of the desalted product does not meet the product quality specification. Thus, a certain amount of the product will be lost to the waste stream.

Electrodialysis Process Costs

The economics of an electrodialysis process are usually expressed as cost per unit product. These costs are the sum of fixed charges associated with amortization of the investment and operating costs such as energy and labour.

Investment costs include items such as the electrodialysis stacks, pumps, electrical equipment and membranes and are proportional to the required membrane area. The minimum required membrane area for a certain plant capacity is

given by:

$$A = \frac{zFQ\Delta Cn}{i\zeta} \quad [24]$$

The required membrane area for a given capacity electrodialysis plant is proportional to the amount of ions removed from a given feed solution and inversely proportional to the applied current density.

As indicated earlier, the applied current density should not exceed a certain limiting value. According to eqn [23] this value is proportional to the diluate concentration and the mass transfer in the boundary layers at the membrane surfaces. The mass transfer depends on the boundary layer thickness, which is a function of flow velocity. For given stack and feed solution properties, the limiting current density is given by:

$$i_{\text{lim}} = {}^{\text{bd}}C_s a u^b \quad [25]$$

Here a and b are constants, the values of which are determined by a series of parameters such as the cell and spacer geometry, the solution viscosity and the transference numbers of ions in the membrane and the solution.

Eqn [25] shows that the limiting current density is proportional to the diluate concentration. However, the diluate concentration is changing during the desalting process from the concentration of the feed to that of the product. Thus, the limiting current density is decreasing along the flow path through the stack. The average limiting current density is proportional to the average concentration in the diluate cell and

Figure 7 Membrane, energy and total costs of the actual desalination process in electrodialysis.

given by:

$$\bar{i}_{\text{lim}} = {}^{\text{bd}}\bar{C}_s a u^b = a u^b \frac{{}^{\text{bd}}C_s^{\text{co}} - {}^{\text{bd}}C_s^{\text{cp}}}{\log \frac{{}^{\text{bd}}C_s^{\text{co}}}{{}^{\text{bd}}C_s^{\text{cp}}}} \quad [26]$$

Combining eqns [24] and [26] leads to:

$$A_{\text{min}} = a' \frac{\log \frac{{}^{\text{bd}}C_s^{\text{co}}}{{}^{\text{bd}}C_s^{\text{cp}}}}{{}^{\text{bd}}C_s^{\text{co}} - {}^{\text{bd}}C_s^{\text{cp}}} \quad [27]$$

The constant a' is determined by the feed flow velocity, the stack design, etc.

The operating costs of an electrodialysis plant are mainly determined by the energy consumption which is the sum of the electrical energy required for the ion transfer and the energy necessary for pumping the solution through the stack, as indicated in eqns [17] and [18]. The energy required for the desalting process is a function of the feed solution concentration. The pumping energy depends on the flow velocities in the stack.

It should be noted that, according to eqn [12], the energy costs increase with increasing current density, while the required membrane area decreases with increasing current density. Thus the total desalination cost – which is the sum of capital, energy and operating costs – will reach a minimum at a certain current density, as illustrated in Figure 7, where the total cost of an electrodialysis process is shown schematically as a function of the applied current density.

Applications of Electrodialysis

Electrodialysis is mainly used to desalinate saline solutions such as brackish water. But other applications such as the treatment of industrial effluents, demineralization of whey and deacidification of fruit

juices are becoming increasingly important. In Japan, electrodialysis is also used in the production of table salt from sea water.

Desalination of Brackish Water by Electrodialysis

In terms of installed plant capacity, the most important application of electrodialysis is the production of potable water from brackish water. Here, electrodialysis competes directly with reverse osmosis and multistage flash evaporation. For water with a relatively low salt concentration (less than 5000 p.p.m.), electrodialysis is generally considered to be the cheapest process. Another significant feature of electrodialysis is that salts can be concentrated to comparatively high values without affecting the economics of the process severely.

Production of Table Salt

In the production of table salt from sea water, electrodialysis is used to concentrate sodium chloride up to 200 g L^{-1} prior to evaporation. This application is developed and used nearly exclusively in Japan. Key to the success of electrodialysis in this application has been the development of membranes with a preferred permeability of monovalent ions.

Electrodialysis in Waste Water Treatment

Treatment of metal ion-contaminated rinse waters produced in electroplating operations is an important application of electrodialysis. Complete recycling of the water and the metal ions can be achieved in favourable cases. A disadvantage, however, is that in electrodialysis only ions can be removed from a feed stream. Uncharged components that are also present in the rinse waters cannot be recovered.

Dump leach waters containing heavy metal ions have also been successfully treated by electrodialysis. The removal of nitrate from drinking water by electrodialysis is an application that seems to be competitive to processes such as ion exchange or reverse osmosis.

While in most of these applications the average plant capacity is considerably lower than that in brackish water desalination or table salt production, there is also a significant number of large plants installed for the treatment of refinery effluents and cooling-tower waste streams.

Concentration of Reverse Osmosis Brines

Often the disposal of large volumes of brine obtained in reverse osmosis plants is difficult and further concentration is desirable. Because of the osmotic pressure, the brine concentration cannot exceed a certain value in reverse osmosis. A further

concentration, however, may be achieved at reasonable cost by electrodialysis.

Electrodialysis in the Food and Chemical Industry

Several applications of electrodialysis in the food industries, such as the demineralization of cheese whey, have considerable economic significance and are well established today. Other applications, such as the deashing of molasses or de-acidification of fruit juices, are still in an experimental stage. In the chemical industry electrodialysis is used for the desalination of protein, dextran or sugar solutions. Here, electrodialysis is often in competition with other separation procedures such as dialysis and solvent extraction. The separation of organic acids is an application of electrodialysis that is of interest to the pharmaceutical industry.

Production of Ultra Pure Water

Electrodialysis is now being used for the production of ultra pure water for the semiconductor industry. By combining electrodialysis with mixed-bed ion exchange resins, deionized water is obtained without a chemical regeneration of the ion exchange resin. The process has been commercialized recently.

Conclusions

Electrodialysis has a long and proven history in the desalination of brackish waters. However, new applications in waste water treatment as well as in the

food and the chemical industry are becoming more and more important. There are still a multitude of problems to be solved. Some are related to the properties of the membranes and the process design, while others are caused by the lack of application know-how and practical experience.

Introduction

Filtration is a key processing operation in the pharmaceutical, chemical and cosmetic industries. For example, filtration may be necessary to clear process solutions before analysis or as process step in manufacturing or in the sterilization of process solutions. Analytical testing requires only laboratory-scale filtration and is usually performed by a variety of membrane types depending upon the application. Filtration in manufacturing requires large-scale filtering in engineered devices called membrane modules or cartridges.

Filtration Mechanism

Filtration is a mechanical phenomenon, which is sometimes aided by chemical manipulations of the filtration medium to make it more efficient. In any case, a driving force across the filter media is required. The following methods can be used to generate this driving force:

- Vacuum
- Pressure difference
- Centrifugal force
- Gravity pull
- Concentration difference
- Electrical potential difference
- Temperature difference
- A specific chemical attraction–repulsion

concentration, however, may be achieved at reasonable cost by electrodialysis.

Introduction

Filtration is a key processing operation in the pharmaceutical, chemical and cosmetic industries. For example, filtration may be necessary to clear process solutions before analysis or as process step in manufacturing or in the sterilization of process solutions. Analytical testing requires only laboratory-scale filtration and is usually performed by a variety of membrane types depending upon the application. Filtration in manufacturing requires large-scale filtering in engineered devices called membrane modules or cartridges.

Filtration Mechanism

Filtration is a mechanical phenomenon, which is sometimes aided by chemical manipulations of the filtration medium to make it more efficient. In any case, a driving force across the filter media is required. The following methods can be used to generate this driving force:

- Vacuum
- Pressure difference
- Centrifugal force
- Gravity pull
- Concentration difference
- Electrical potential difference
- Temperature difference
- A specific chemical attraction–repulsion

Filtration is either through a membrane or bed of filter media. The chemical composition of the filter media and physical conditions to perform the filtration constitute a large number of filtration choices available today.

Membrane Filtration

Membrane filtration through a very thin filter medium is also known as 'surface filtration'. The solid particles to be separated are usually large compared to the pore size characteristic of the membrane. The pores on the surface are of irregular shapes. The rejection of particles is dependent on several factors affecting the transport through these pores into the tortuous channels. The separation is based on exclusion discrimination by physical size, charge or affinity or a combination of these properties. Large particles are rejected on the surface and do not accumulate on the surface and do not get a chance to enter into the interior of the filter.

Other types of membrane filters are screen filters and here the pores do not lead into tortuous capillary paths. The pore size is uniform but the distribution of the pores is random on the filter surface. The filter is made by bombarding a thin polycarbonate film with neutrons in a reactor. The film is then placed in a bath of etching solution which preferentially attacks the polymer along the track of the neutrons. The pore size is regulated by selecting the appropriate reagent, exposure time and temperature.

Membrane filtration can be dead end or cross-flow. In dead-end filtration all the solution is forced through the membrane. Retained particles collect on the membrane surface and in the filter greatly reducing flow. A current application of dead-end filtration is in bacterial testing where the liquid to be tested is passed through the filter retaining all bacteria on the surface. Most chromatographic filtration applications are of this type. In cross-flow membrane filtration, the feed liquid flows tangentially to the membrane surface, which prevents the build up of cake on the membrane. Both types of filtration use similar membranes.

By convention, membrane filtration or microfiltration is limited to membranes used to remove particles larger than 0.1 μm in diameter. Membranes able to remove smaller particles are called 'ultrafiltration membranes' and microsolute can be removed by reverse osmosis. Ultrafiltration and reverse osmosis are discussed elsewhere. This article is limited to the process of microfiltration.

The filtration thresholds of common membrane-filtration processes are shown in Table 1.

Table 1 Filtration threshold of common membrane-filtration processes

<i>Type of filtration</i>	<i>Impermeability of membrane</i>
Reverse osmosis	< 0.001 μm
Ultrafiltration	0.001–0.1 μm
Microfiltration	0.1–10 μm

Microfiltration

Microfiltration is used to separate suspended solids or colloidal particles between 0.1 and 10 μm in diameter from solution. Most of the chromatography applications are microfiltration based. The same type of membrane with different pore size is used for these applications. The membrane acts like a physical sieve. The fluid passes through tortuous channels while the particles are rejected on the surface of the filter. It can be easily understood as a mechanical sieve with pores leading into a capillary forming a tortuous path; within this tortuous path, there could be mechanical entrapment and adsorption (Figure 1).

Microfiltration membranes can be subjected to harsher conditions compared to ultrafiltration membranes. Membranes of different polymers in varying pore sizes are available. Even nominally the same pore-size membranes of a polymer may differ from each other in filtration characteristics because they may have different pore-size distributions, i.e. varying pore size all across the membrane. To aid in wetting, many membranes have some surfactant pretreatment and their effective pore size may be different from the real pore size. Often a membrane filter becomes more efficient as small particles are entrapped within the pores. The large particles captured on the filter can also alter the effective particle-size rejection in subsequent filtration. Filter capacity may vary depending on the solute particle-size variation in the feed. Uniform size particles result in faster clogging of filters.

Depth Filter

In depth filtration, the filter medium has larger pores than the particles it is meant to remove. The process starts out at the surface of the filter and proceeds in the cake portion of the membrane. The medium traps the particles in the interstices of the internal structure. Particles enter into the filter medium and separate by gravity settling, diffusion, and attachment to the media owing to electrostatic forces. These filters usually have a pressure drop across the filter caused by pressure, vacuum, or centrifugation. These filters usually have a long life, but

Figure 1 Tortuous path of micro- and ultrafiltration.

eventually a cake is formed over the medium stopping the flow through the filtration device. When the filter bed is full of solids and the pressure drop is very high, the entrapped solids can be back-washed. Usually less than 0.1% solids concentration is filtered through this type of filter to avoid pressure build up. There is always some liquid left behind in depth filters and some solid material still makes it through the filter medium depending upon the efficiency of the system. To use the system effectively, variations of this procedure using moving-bed filters, radial flow filters, or travelling back-wash filters can be employed. The commercial products available for this kind of filtration are application specific.

Filtration Matrices

A variety of polymers are used to manufacture filter media. Each type has specific attributes and could be best for certain applications but could be a complete failure for other applications. The same filter material from different manufacturers can differ in physical properties and in filtration characteristics. However, the chemical compatibility of the material is almost the same irrespective of the manufacturer (Table 2).

Incompatible chemicals can cause shedding, affecting pore size, as well as adding extractables. Hydrophobic membranes have to be wet before starting the filtration. In some cases, it is desirable to convert the hydrophobic membranes into hydrophilic membranes by modifying the surface. Surface reactions can also be used for changing the surface charge. The

polyvinylidene fluoride (PVDF) membranes can be treated to render them hydrophilic and can be reacted to modify the surface charge. The use of aggressive solvents should be avoided with these filters to minimize deterioration of the surface. Membranes used in filtration usually have surface-active agents incorporated in them to make the pre-wetting easier.

Filtration Devices

The filtration application dictates the type of device to be used. Industrial applications demand a high surface area, ease of cleaning and low clogging. For enhanced yield and capacity, open-channel tangential flow systems, which require two pumps for recirculation and permeation, are available from several manufacturers. Different designs are used to overcome gel formation and to continuously sweep away the contamination in the filtration process. The details of these systems are beyond the scope of this article.

The most common disposable filtration devices used in laboratories are syringe filters. The membrane is held in a polypropylene housing with an adapter for syringe attachment on one end. This adapter can be a luer lock or friction fitting. The other end is designed for easy extrusion of permeates. The filter membrane can be housed alone or with pre-filters. The membrane is bonded to the housing ultrasonically, without the use of any chemical adhesive, to avoid unwanted extractables in the filtering process. Syringe filters are disposable and used in very high volume, particularly in the pharmaceutical industry. Because the continuous use of syringe filters

can be tiring, a mechanical device is now available which is helpful when repeated filtration is required.

Another common type of laboratory filtration is with centrifuge filters. These devices are the method of choice for molecular weight cut-off filtration and for the filtration of viscous materials. The driving force here is centrifugal force. The filter is manufactured to fit in the rotors of laboratory centrifuges. In these rotors, several filtrations can be carried out simultaneously.

Filtration Applications

In every type of filtration process, the result is always a retentate (restricted to pass through the filter media) and permeate (down stream collection). Retentate or permeate can be the desired product of the process.

Selective Filtration

Selective filtration is used to retain only a particular type of solute. Usually in these cases membranes are

modified for the desired affinity. There are several applications and products available based on ionic attraction.

Purifying Water

The constantly increasing demand for drinking water requires the sea or other sources to be converted into potable water. Most of the potable water plants use reverse-osmosis treatment. Water used in injectables, buffers and chromatography generally has very defined specifications. For most laboratory applications, water with an electrical resistance of not less than 18 MΩ is required to be pyrogen- and bacteria-free. The water used in chromatography should be free of UV/vis-absorbing and ionic impurities.

Chromatographic Applications

Filtration is required in chromatography for preparing a sample for injection. The preparation may include concentration and/or purification. Sample filtration helps in trouble-free operation of chromatography instruments and columns. The use of filtration

for processing samples and solvent is an essential part of instrument preventive maintenance programmes. The filtration of the mobile phase also results in degassing, which is essential for long pump life in high pressure liquid chromatography. The most common devices used for sample preparations are syringe filters.

Biological Applications

The use of filtration as a sterilizing technique is becoming increasingly popular. Other sterilization techniques such as autoclaving, radioactive exposure or ethylene oxide treatment can be detrimental for the product. A dead-end filtration using 0.22 μm pore-sized membrane is considered good for sterilizing by filtration. Viruses can permeate through the membrane of 0.22 μm filter. A 0.1 μm pore-size filter is used to prepare a virus-free solution.

Filtration is also used for desalting or buffer exchange of proteins and nucleic acids, deproteinizing samples, screening natural products and combinatorial products, and separation of oligonucleotide primers from nucleic acid preparations.

Selecting the Right Filtration System

Each application requires a specific filtration characteristic. Choosing the right filtration device and media are necessary when selecting the correct filtration system. The following considerations help when deciding which filter device is to be used:

- Objective of filtration.
- Sample size.
- Filter parameters required: permeability, capacity and flow rate.
- Physical conditions to which the filtration is required to be subjected.
- Tangential flow filter or dead-end filter.

The choice of filter material, pore size and physical conditions depends on the following factors:

- The chemical and physical condition of the feed.
- Size and shape of molecules.
- Zeta potential and isoelectric point. Filtration carried out at a pH close to the isoelectric point results in reduced electrostatic interactions.
- Hydrophobicity or hydrophilicity.
- Solvent in which solute is dissolved.
- Properties of the filter feed, pH, viscosity, surface tension, ionic strength, osmolarity and chemical functionality.
- Intended use after filtration of the sample

Choice is always application specific. For example, in the bacterial examination of water, the purpose is to retain all the particles on the filter surface. A dead-end filtration is used on a 0.2 μm filter. The cross-flow filter is useful for concentrating particles with the removal of solvent. In selecting the filtration system, it is necessary to always consider yield, simplicity, technical reasons and cost.

In some applications, using a combination of different filtration techniques in a certain order is the most efficient method. Sometimes it helps to pretreat the solution to be filtered. The pretreatment could include coagulation and flocculation, magnetic treatment, pH adjustments, and an electric field. A proper washing procedure is usually employed to have the most efficient filtration.

Two filters supplied by Pall Corporation are shown in Figures 2 and 3.

Filtration Validation

The validation of filtration processes includes all the equipment, physical conditions and material requirements of the process. Usually the filter manufacturer performs the basic testing to ensure the type, pore size and integrity of the filter. The filter material characteristics are covered in this article. Some of the most common tests used for this purpose are shown below.

Bubble Point

Bubble point is a function of pore size, filter medium wettability, surface tension and angle of contact. The filter membrane is wetted and a gradual increasing gas pressure is applied. The bubble starts forming from the largest pore first. The gas pressure at this time is the bubble point for the membrane. This is an indirect measurement of the size of the largest pore on the filter. It does not indicate the variability of pore sizes or irregularity of the membrane.

Water Breakthrough

The water-breakthrough test is used for hydrophobic membranes. It is similar to bubble point as this test also give information about the largest pore of the filter membrane. In this test, the minimum pressure required to permeate water from a filter membrane is measured. The water-breakthrough number is dependent on pre-wetting, temperature and pore size of the filter medium. Water is first permeated from the largest pore. This also ascertains filter usability as an aqueous barrier.

Figure 2 (See Colour Plate 49). Pall Ultipor® VF™ Grade DV50 virus filters for high protein-transmissible virus filtration. (Photo courtesy of Pall Corporation, East Hills, NY.)

Extractables

The filter devices and materials can be a source of contamination in the filtration process. The source of impurities could be additives, stabilizers, surface modifiers, detergents and monomers in the filter material. Some contaminants occur in small quantities but some detergents can make up as much as 2–3% of the dry weight of the filter. This large amount of detergent helps in efficient filtration, lower pressure requirements and permits autoclaving for sterilization. The additives and monomers can be entrapped within the body of the filter. Sometimes the source of impurities is not from the filtering material but from the housing or support of the filter. This housing material is usually plastic, and the manufacturer tests that the plastic used in containing the filter material is not going to leach out impurities under

experimental conditions. Although aggressive solvents or physical conditions may be very compatible with the filter membrane, they may affect the filter-containment system.

In some analyses, even a small amount of contaminant is enough to cause problems. Commercial filter manufacturers now certify for specific applications. For many biological applications, the manufacturer certifies the filtration material to be pyrogen-free. For chromatographic applications the filter material is certified not to add impurities to the process. The safest way to use filters for chromatography is to wash them with the same solvent used during filtration and to discard an initial volume of the filtrate. The filters used in ion analysis should be completely free of any ionic impurities. The standard operating procedure of the filtration step should clearly define the conditions and if possible include the limits of the procedure.

Figure 3 (See Colour Plate 50). Pall Ultiplex® high flow filters, providing efficient and economical high-flow filtration with reduced waste disposal costs. (Photo courtesy of Pall Corporation, East Hills, NY.)

Flow Rate

The flow rate is determined by using water or alcohol to determine the permeability to flow before any extra pressure drop produced by the filter cake. Flow rate is dependent on the hydrophobicity of the filter material, temperature of the procedure, physical thickness and pore-size distribution of the filter material. It is expressed as millilitres per minute per square centimeter. An optimum flow rate is needed for the expected life of a filter.

Capacity

Capacity of filtration is the ability to maintain an acceptable permeability. The capacity of a filter is measured until an increase of about three times in differential pressure or ~60% decrease of initial flow. It is expressed as time, volume of liquid, or by quantity of retained particles.

Pore Size

Pore size is probably the most misunderstood property of the filter membrane. The estimation of pore size depends upon the method employed to determine the porosity. The usual methods are all indirect. For

a nominal rating, a range of neutral polymers of different sizes is challenged individually on the membrane and the percentage of a particular size retained on the surface rates it for that size. It could be anywhere from 60 to 98% for a given size rating by the manufacturer. The variability of pore sizes is also polymer dependent. The pore sizes are irregular in membranes manufactured by solvent casting. The pore size is averaged to give a mean pore size assuming all pores are circular. The importance of this point is that the efficiency of the filter should be measured above this point. In actual practice, pore size is used only as a guide; retained particle size data are closer to reality in the filtration process. Most filter manufacturers give particle size retained data traceable to standards from the National Institute of Standards and Testing. In membranes manufactured by neutron bombardment, the pores are circular and same-size pores are randomly distributed along the surface of the membrane. The pore size given is the actual pore size of the membrane. In many filter membranes, detergents are used for enhancing filter characteristics; the effective pore size in these membranes is usually larger than the actual pore size.

Microbial Challenge Test

The absolute rating of a membrane is determined by challenging with test organisms (Table 3). The volume of the feed is such that it averages out to one organism per pore on the membrane surface. The absolute rated membrane is accepted if no more than one organism is present in the permeate.

A membrane with a pre-rating of 0.22 μm is acceptable for liquid filtration sterilization. The ability of a membrane to remove bacteria is dependent on the size of the pores and the thickness of the membrane. There is a finite number of specific bacteria, which can be retained by the membrane before it becomes effectively clogged.

Filtration Challenges

Despite the fact that a great deal of improvement in the filtration process and material has taken place,

Table 3 Microfiltration rating by test organisms

Microfiltration rating	Test organism
1 μm	<i>Candida albicans</i>
0.8 μm	<i>Lactobacillus</i>
0.45 μm	<i>Serratia marcescens</i>
0.2 μm	<i>Pseudomonas diminuta</i>
0.1 μm	<i>Acholeplasma laidlawii</i>

there are still some areas where any advancement will make filtration a friendlier process.

Scaling Up for Manufacturing

The filtration process development remains a challenge because the efficient separation at small volume level is not always transferable to pilot or production scale with the same efficiency and chemistry. Several manufacturers claim new scalable technologies providing similar results in large scale as applications using tangential flow with the same fibre material used throughout the development of the filtration process. Special filtration scale-up software is available commercially.

Membrane Fouling, Gel and Cake Formation

The filtration membranes may start fouling during use. This means that particles start attaching on the surface and in the internal porous structure of the membrane. Large suspended or colloidal particles usually are the cause of fouling. Fouling is a result of van der Waals forces, electrostatic attraction, or hydrogen bonding. The fouling of filter media results in a reduction in membrane permeability and uncontrolled solute removal efficiency. The pretreatment of the feed can be helpful in delaying or completely avoiding fouling. Gel formation and cake formation on the surface can be reversible and filter media can be reused. Macromolecules and some interacting small organic molecules can result in gel formation on the filtration surface.

Cleaning the Filter Media

It is not cost effective to clean the filter in laboratory-scale filtration. For large-scale filtration, usually cleaning and validation protocols are used. The cleaning process could involve cleaning with detergents or other strong chemicals. It could also involve treating with proteolytic enzymes to break down protein impurities trapped in the filter medium and EDTA to arrest activity of bacterial enzymes. Development of cleaning procedures and validation of filter media is very application specific and requires experienced people to design and implement.

Extractables

The extractables in the filter medium can create a problem in the subsequent use of the permeate. This remains a problem in some filter media where additives are used for improved performance. The origin of extractables is either in the processing or the housing device of the filter. Various kinds of extractables are found, including metals, oligomers, loose polymers, plasticizers, wetting agents, antioxidants,

resins, fillers and mould-release chemicals. The usual practice is to wash off the filter material immediately before use. The type and amount of impurity in filter media is not consistent. Each type of impurity has its own rate of extraction from the medium. Hence there is no universal filter-treatment procedure which can ensure a contamination-free permeate. The washing procedure could be under- or overdone in certain applications. The challenge exists to manufacture consistent contamination-free filter media.

Conclusion

Tremendous developments have taken place in both laboratory and large scale filtration techniques in recent years. Various new types of matrices have been exploited for filtration applications. The heavy use of filtration in industry has clearly identified the challenges that remain to be solved. Research continues on selective filtration as a cost-effective way of separation for various applications. In the next few years, we will witness improvement in both the chemical and mechanical properties of filtration equipment.

Gas Separations with Polymer Membranes

Copyright © 2000 Academic Press

Introduction

In 1996 the worldwide industrial gas market was in excess of \$29 billion (US). It continues to grow at an average rate of 4–5% per annum. Industrial gases account for some of the largest production volume chemicals (1998 US): nitrogen (843 bcf (billion cubic feet)), oxygen (698 bcf) and ammonia (19 700 million tons). Oxygen and nitrogen are separated from purified air. Ammonia is produced by the reaction of nitrogen and hydrogen. Certainly, the vast majority of industrial gases are purified using cryogenic distillation or adsorption technology. However, in the last 20 years there has been a growing interest in and an intense effort on the part of major gas producers to evaluate and develop membrane technology to produce or purify gases. By 1999 sales of gas separation membrane technology exceeded \$100 million per year. This article will describe basic concepts along with various practical aspects of polymeric gas separation membranes including permeability measurement, membrane formation, module fabrication and applications.

A polymeric membrane is defined as a thin, semipermeable barrier between two gaseous phases. Gases will permeate the membrane if a difference in their chemical potential exists between the two gaseous phases. The chemical potential difference is most often a result of pressure differences across the membrane. Thus, gases will solubilize into the membrane at the high pressure interface, diffuse across the membrane in a concentration gradient to the low pressure interface and evolve into the low pressure gas phase (Figure 1). If a mixture of gases comprised of components *i* and *j* is brought into contact with the membrane, the permeate stream will be enriched in the more permeable gas *i*, leaving the retentate enriched in gas *j*.

The realization that gases permeate through polymers is not new. Every child knows that a balloon filled with air or helium deflates over time. Indeed, this phenomenon was observed by Mitchell in 1831. Balloons made of natural rubber filled at different rates depending on the gaseous atmosphere they were placed into. Carbon dioxide filled the balloon fastest, air slowest. Thirty-five years later Graham expanded

on Mitchell's experiments and quantitatively measured the permeation rates of gases through natural rubber. He found that the permeation rate was not related to the known *gaseous* diffusion coefficients and so concluded that permeation does not proceed through microscopic pores in the rubber but must occur within the rubber itself. He also demonstrated that natural rubber could be used to produce from air a permeate which was enriched in oxygen to 46%.

A mathematical description of the permeation process was proposed by Fick. The relationship between permeation rate *J*, gas pressure *P*, membrane area *A* and membrane thickness *l*, known as Fick's first law, is governed by eqn [1], where ΔP is the pressure difference across the membrane:

$$J = P_o \cdot A \cdot \Delta P / l \quad [1]$$

The proportionality constant, P_o , is termed the permeability:

$$P_o = \frac{J \cdot l}{A \cdot \Delta P} = \frac{\text{volume gas} \cdot \text{thickness}}{\text{area} \cdot \text{time} \cdot \Delta P} \quad [2]$$

The customary unit of permeability is the barrer where:

$$1 \text{ barrer} = 10^{-10} \frac{\text{cm}^3 \cdot \text{cm}}{\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}} \quad [3]$$

Permeability can also be written as the product of the gas solubility times its diffusivity, the so-called *solution-diffusion* mechanism (eqn [4]). The permselectivity (α) for two gases *i* and *j* is defined as the ratio of the permeabilities:

$$P_o = D \cdot S \quad [4]$$

$$\alpha_{ij} = P_{o_i} / P_{o_j} \quad [5]$$

Figure 1 Schematic representation of membrane permeation.

Permeation is an activated process. The effect of temperature on permeation is given by eqn [6], where E_p is the activation energy of permeation, R is the gas constant and T is temperature:

$$P_o = P'_o \cdot \exp(-E_p/RT) \quad [6]$$

In typically encountered cases E_p is positive and the permeability increases exponentially with temperature. Additionally, E_p is related to penetrant size and therefore selectivity usually decreases with increasing temperature. This treatment is not true when dealing with gases below their critical temperature. The reader is referred to the Further Reading section for these special cases.

The above equations give a mathematical, phenomenological description of gas permeation through polymers but imply nothing of the molecular-level processes giving rise to permeation. While we speak of gas-separating polymers as being dense films, on a molecular level one must consider that the membrane is not 'solid'; that is, there are molecular-size gaps between the polymer chains. These gaps arise from packing defects in the solid state and also arise from the thermal motions of the polymer chains themselves. It is through permanent and transient gaps that gas transport is believed to occur. Solution-diffusion behaviour has proven adequate to describe permeation through rubbery polymers – those whose glass transition temperature, T_g , is below the experimental temperature. As a family, rubbery materials are highly permeable but unselective for the same molecular-level rationalization. In the rubbery state polymer chains are highly mobile, generating a high frequency of transient gaps which the penetrant gases can easily diffuse through. However, these gaps are not very selective. From a practical perspective, the purity of the product is related to the membrane permselectivity. With some exceptions, such as the

Figure 2 Schematic of free volume.

Figure 3 Dual-mode sorption isotherm.

production of oxygen-enriched air for medical applications or the recovery of C4 hydrocarbons, low-selectivity membranes and hence rubbery polymers have found limited commercial utility in the purification of industrial gases.

Dual-Mode Permeation in Glassy Polymers

Polymers in the glassy state possess 'free volume' as shown in Figure 2 – that is, a polymer quenched below its T_g to a nonequilibrium state in which its molar volume is higher than the equilibrium value. This free volume can be visualized as long-lived molecular-level gaps between the polymer chains. One aspect of free volume is that glassy polymers exhibit excess sorption capacity. Sorption in glassy polymers can be described by eqn [7]:

$$S = k_D P + \frac{C'_H b P}{1 + b P} \quad [7]$$

Figure 4 Coupling of Langmuir and Henry's mode diffusion coefficients.

Figure 5 Permeability test cells. A, supporting legs; B, lower plate; C, upper plate; D, adapter; E, vacuum valve.

where k_D is the Henry's law solubility constant, b is the Langmuir equilibrium constant and C'_H is the Langmuir capacity and can be related to the free volume. Such sorption is often termed 'dual-mode'

behavior. A typical dual-mode sorption isotherm is shown in Figure 3. At low pressures, sorption is dominated by the Langmuir element, while at high pressure sorption is described by Henry's law.

Figure 6 Time lag diffusion experiment.

Dual-mode permeation can be viewed as the simultaneous diffusion of gas molecules within and between the dense polymer phase and the Langmuir gaps or 'holes'. Dual-mode permeation then is described by the sum of permeation in these phases (eqn [8]). The two diffusion coefficients D_D and D_H appear to be strongly correlated to each other (Figure 4):

$$P_o = P_o(\text{dense}) + P_o(\text{hole}) = S_D D_D + S_H D_H$$

$$P_o = k_D D_D + \frac{C_H b D_H}{1 + bP} \quad [8]$$

Some consequences of dual-mode transport are:

1. The permeability of a dual-mode system decreases as the pressure is increased.

Table 1 Air separation characteristics of some common polymers

Polymer	P_{O_2} (barrer)	α_{O_2/N_2}
Polyacrylonitrile	0.0002	>10
Polyvinylidene chloride	0.0053	5.6
Polyethylene terephthalate	0.059	4.5
Cellulose acetate	0.78	2.8
Polystyrene	2.63	3.3
Poly(4-methyl-1-pentene)	32.3	4.1
Silicone rubber	610	2.0
Poly(trimethylsilylpropylene)	8000	1.4

2. Condensable vapours such as water and higher hydrocarbons are strongly adsorbed in the high enthalpy free volume sites and deleteriously affect permeation rates and permselectivity.
3. Strongly absorbing gases such as CO_2 can swell the membrane at high pressure.
4. The free volume, a manifestation of the non-equilibrium state of the polymer, can be decreased by annealing or upon aging.

Methods of Measuring Permeability

Conceptually, measuring the gas permeability of polymeric membranes is simple although fraught with experimental pitfalls related to establishing steady state flow. The experimental parameters are given in eqn [2]. Several methods and apparatus have been developed to conduct permeability measurements. For obtaining the permeation pure gases one

Figure 7 Upper bound representation of oxygen/nitrogen permselectivity - 1990.

Lennard-Jones kinetic diameters of various gases

Gas	He	H ₂	CO ₂	O ₂	N ₂	CH ₄

measurers either the rate of permeability pressure rise (usually from a vacuum) in a constant volume/temperature receiver or the volume of permeate gas at a fixed pressure (Figure 5). Commercially available test cells are known as the volumetric or 'Linde cell' and the manometric or 'Dow' cell. The American Society of Testing and Materials has published a method for measuring gas permeability (ASTM Method D1434-82). It is possible to obtain the

Table 2 Upper bound parameters

$P_i = k\alpha_{ij}^n$ Gas pair (ij)	k (barrer)	n
O ₂ /N ₂	389 224	-5.800
H ₂ /CH ₄	18 500	-1.2112
CO ₂ /CH ₄	1 073 700	-2.6264
He/N ₂	12 500	-1.0242

permeability coefficient P_0 and the diffusion coefficient D through a *time lag* measurement as shown in Figure 6; subsequent calculation of the solubility term though an independent measurement of S is advised.

Measuring the permeability of gas mixtures is more complex. Usually a flow of a pre-blended source is passed over the feed side of the membrane. The steady state permeate flux can be measured by employing an inert gas such as helium to sweep the permeating components into a gas chromatograph, for example, for compositional analysis. Preferably the experiment is conducted such that back-diffusion of the helium sweep is insignificant and where the feed gas composition is not altered by permeation. Additionally, nuances in the flow patterns within test cells not specifically designed for mixed gas experiments can lead to erroneous results.

Optimization of Polymer Permeation Properties

common polymers. Permeability spans a wide range: seven orders of magnitude. Further, as the permeability of polymers increases, their ability to differentiate between gases, the permselectivity, decreases. This correlation is valid for nearly all polymeric membranes and has been the subject of research. While long recognized, this observation was first formalized by Robeson in 1991. Working with a database of over 200 polymers, the selectivity of several gas pairs, plotted on a log-log scale against the permeability of the faster gas, exhibits a characteristic upper bound defining the combinations of permeability and permselectivity simultaneously achievable with polymeric materials (Figure 7). Upper bound performance can be described by eqn [9]:

$$P_i = k\alpha_{ij}^n \quad \text{or} \quad \alpha_{ij} = k^{-1/n} P_i^{1/n} \quad [9]$$

where the values of k and n , tabulated in Table 2, are calculated from the upper bound relationship for specific gas pairs. The parameter n is related to the difference in kinetic diameters of the penetrant gas pair Δd_{ij} as shown in Figure 8. This empirical treatment implies that the upper bound is a natural result of the sieving characteristic of stiff chain glassy polymers. A fundamental theory was later developed by Freeman in which the constants could be related to gas size and gas condensability and invoked just a single adjustable parameter f :

$$\ln \alpha_{ij} = -\lambda_{ij} \ln D_i + \{\ln (S_i/S_j) - \lambda_{ij}(b - f(1 - a)/RT)\} \quad [10]$$

where $\lambda_{ij} = [(d_i/d_j)^2 - 1]$ and d_i is the kinetic diameter; $S_i/S_j = N(\varepsilon_i/k - \varepsilon_j/k)$, where k is the Boltzmann constant and ε is the potential energy well depth in the Lennard-Jones potential energy function. The constants a and b are derived from linear free energy relationships and are independent of gas type. Moreover a is independent of polymer and has a universal value of 0.64; b has a value of 11.5 for glassy polymers and 9.2 for rubbery polymers. The solubility selectivity among polymers is largely constant; consequently diffusivity considerations dominate upper bound permselectivity.

The optimization of polymer structure to obtain upper bound properties comprises the lion's share of polymer membrane research in the last 20 years and the reader is referred to the Further Reading section. Researchers have heuristically developed the understanding gained via the upper bound analysis. The permselectivity for gases i and j is given by eqns [4] and [5] as:

$$\alpha_{ij} = P_{O_i}/P_{O_j} = (S_i/S_j) \cdot (D_i/D_j) \quad [11]$$

Groups are defined volume of atoms within shaded areas

Groups are defined by volume of atoms between lines

Figure 10 Structure-property relationship: (A) FFV model (Paul). (B) Robeson model.

The solubility selectivity (S_i/S_j) is nearly constant across a wide variety of polymers and for O_2/N_2 is about 2. Selectivity in glassy polymers is therefore dominated by the diffusive selectivity which in turn results from the sieving properties of the imperfectly packed polymer chains. The best trade-off in permeability properties within a polymer family is obtained when both main chain mobility is limited and intersegmental packing of polymer chains is

Figure 11 Structure units with imparting superior permselectivity.

Figure 12 Cross-section of an asymmetric membrane.

inhibited. This behaviour is illustrated (Table 3) for a family of pyromellitic dianhydride (PMDA) and hexafluoro-isopropylidene dianhydride (6FDA)-based polyimides. Changes in the functionality lead to different packing arrangements as measured by density and X-ray d-spacings (average distance between polymer chains). Very small changes in chain packing result in significant changes in both permeability and selectivity. Further, groups such as 6FDA are particularly desired because they can increase permeability without a large loss of selectivity. A further example is that of *ortho*, di- versus tetra-substitution patterns on aromatic polymers. It is widely recognized that incorporation of bulky substituents leads to an increase in permeability, usually at a loss of selectivity. However, it is also noted that *ortho* di-substitution patterns result in lower permeability and higher selectivity than the symmetrically tetra-substituted analogue. Using this intuitive approach a great many new polymers were synthesized and characterized between 1990 and 1993 and as a result the empirically determined upper bound has been shifted upwards and its slope has changed (Figure 9), with many polymers lying at or near the upper bound.

Predicting Polymer Permeability

The benefit of being able to predict *a priori* the relationship between polymer structure or physical properties and permeability is obvious. One method is to correlate the permeability with the reciprocal of the fractional free volume (FFV), defined as:

$$\text{FFV} = \frac{V - V_0}{V} \quad [12]$$

Figure 13 Phase diagram for a ternary dope system. PP, polymer-poor; PR, polymer-rich; CP, critical point.

where V is the specific volume of the polymer and V_o is the volume occupied by the polymer chains. The specific volume is obtained from experimental density measurement. Direct measurement of V_o is not possible and therefore various computational approaches have been developed. The most widely used is that developed by Bondi relating the zero point volume (the volume occupied at 0 K) to the van der Waals volume of the molecule and later modified by Park to account for the fact that different gases have access to different FFV depending on the specific gas-polymer interaction. This group contribution approach has yielded good correlations (Figure 10A) but it is not intuitively obvious how to relate polymer structure directly to free volume.

The group contribution approach by Robeson asserts that the overall polymer permeability can be represented by the sum of structural subunits that comprise the polymer in proportion to their volume fraction:

$$\ln P_o = \sum \phi_i \cdot P_i \quad [13]$$

where ϕ_i is the volume fraction of subunit i and P_i its permeability contribution. Volume fractions are calculated using molecular mechanics computer modeling and the P_o 's are experimentally determined. The P_i 's are found by regressing the set of simultaneous linear equations from eqn [13]. In addition to adequately representing the experimental data (Figure 10B), this method also identifies those subunits which exhibit upper bound properties

(Figure 11). Desirable moieties include the 6FDA, di-*ortho* substituted phenyl ethers and the spirobi-indane fragment. A superior polymer would be tetrabromo-poly(phenylene oxide); however, no one has as yet succeeded in its synthesis.

Membrane Formation

Most research on polymeric membrane materials is conducted on thin, solvent-cast, films. The practical limit to such membranes is about 25 μm for free-standing films and perhaps 1 μm if the polymer solution is cast on a microporous substrate. However, at these thicknesses the flux through the membrane is too low to be of practical value. That is to say, the economics of a membrane process utilizing these thick films would not effectively compete with established technologies such as cryogenic distillation. The enabling development for fabricating ultrathin, high flux membranes was the integrally skinned asymmetric membrane of Loeb and Sourirajan. This type of membrane is produced by inducing phase separation

Figure 14 Series resistance model for defect repair.

Figure 15 Flat-sheet membrane fabrication.

in a thermodynamically stable solution, usually by changing its composition through the introduction of a nonsolvent. These membranes are prepared by casting a concentrated polymer solution (dope) incorpor-

ating a water-miscible solvent into a water coagulation bath. Such membranes possess an ultrathin dense skin that gradually opens into a microporous substructure (Figure 12). The skin layer provides the

Figure 16 Spiral-wound membrane element.

separation while the thicker integral substructure provides robustness but very little resistance to gas flux.

Membrane formation processes can be grouped into three methods:

1. Dry phase inversion processes involve thermally quenching a dope or solvent evaporation in multi-component solvent system dopes.
2. Wet phase inversion processes involve quenching a cast dope in a coagulation bath.
3. Dry-wet phase inversion processes combine solvent evaporation and a quench medium.

Most commercial gas separation membranes are produced by the dry-wet process although temperature-induced phase inversion (TIPS) is also employed.

Phase diagrams illustrate the phase inversion process (Figure 13). The binodal defines the boundary of the two-phase region and is divided into two parts at the critical point (CP). A second envelope, the spinodal line, also emerges at the critical point. The phase inversion process involves bringing a dope solution into the two-phase envelope. The initially stable solution (at a composition designated by * in Figure 13) decomposes into a polymer-rich phase and a polymer-lean phase, the compositions of which are

defined by tie lines. If the decomposition takes place in the region between the binodal and spinodal a nucleation and growth mechanism of the polymer-rich and polymer-lean phases dominates, leading to structures undesirable for gas separation. Decomposition below the critical point leads to a dispersion of polymer nodules within the polymer-lean phase; decomposition above the critical point leads to a closed cellular structure of an encapsulated polymer-lean phase. The preferred inversion path is to quickly bring the dope within spinodal envelope, thus generating an interpenetrating network of polymer-lean and polymer-rich phases which vitrify into a finely porous substructure.

The thermodynamic framework for a ternary dope system lies in Flory-Huggins theory and the Gibbs free energy of mixing for a ternary system is given by:

$$\Delta G_{\text{mix}} = n_1\phi_1 + n_2\phi_2 + n_3\phi_3 + \chi_{12}n_1\phi_2 + \chi_{13}n_1\phi_3 + \chi_{23}n_2\phi_3 \quad [14]$$

where the subscripts refer to the nonsolvent (1), the solvent (2) and the polymer (3). The notations n_i and ϕ_i are the number of moles and the volume of

Figure 17 Hollow-fibre membrane spinning apparatus and cross-section of spinnerette.

component i and χ_{ij} is the interaction parameter accounting for the nonideality of the mixture. At equilibrium the chemical potentials (u) of the components in all the phases are equal and are given by eqn [15], which defines the binodal envelope. The composition for the spinodal line is given by the solution to eqn [16], where v_i is the pure component molar volume of species i :

$$\frac{\Delta u_i}{RT} = \frac{\delta}{\delta n_i} \frac{\{\Delta G_{\text{mix}}\}}{RT} \quad [15]$$

$$(1/\phi_1 + v_1/v_2\phi_2 - 2\chi_{12})(1/\phi_1 + v_1/v_3\phi_3 - 2\chi_{13}) \\ \times (1/\phi_1 + \chi_{23}v_1/v_2 - \chi_{12} - \chi_{13}) = 0 \quad [16]$$

Composite Membranes

The above discussion also applies to the formation of composite or multilayer membranes. Composite membranes can be categorized as either a dense, isotropic or asymmetric coating of a high performance separating layer on a microporous substrate. Composite membranes are fabricated in two operations, substrate formation followed by dip coating, allowing for the independent optimization of coating and substrate properties. Gas transport through composite membranes is described by the series resistance model by analogy to an electrical circuit. For a two-layer composite consisting of a thin layer of polymer A on a substrate of polymer B, the flux of gas i through the membrane is given by eqn [17], where l is the thickness of the respective layers:

$$J_i = \Delta P(l_B/P_{O_B} + l_A/P_{O_A}) \quad [17]$$

Regardless of their method of formation a critical element of gas separation membranes is that the skin layer must be as thin as possible in order to produce a high flux membrane. The practical limit to the skin layer thickness is thought to be in the range of 500–1000 Å. Concurrently, the skin layer must be free of manufacturing defects or pinholes. A defective surface area fraction as low as $10^{-5}\%$ can lower selectivity to an extent that the membrane is not suitable for gas separation. Conventional manufacturing processes are not capable of achieving this level of reliability. The second enabling development in commercializing gas separation membrane technology was the demonstration of a poly(dimethylsiloxane) defect repair coating to effectively ‘plug’ manufacturing pinholes and eliminate bulk flow through the defects (Figure 14). Gas permeation through this multicomponent system is described by the series resistance model analogous to an electrical

Figure 18 Hollow-fibre membrane element.

circuit. The total resistance is given by the sum resistances in the coating layer (R_c); the parallel resistance in the defective skin layer; ($R_{sk,d}$); and the resistance of the substrate R_{sub} :

$$R_{\text{tot}} = R_c + R_{sk,d} + R_{sub} \\ = R_c + \frac{R_{sk} \times R_d}{R_{sk} + R_d} + R_{sub} \quad [18]$$

After repair, the resistance of the defect, R'_d is greater than R_d and also, $R_{sk} > R'_d$, so that the effective permeability of the composite approaches the intrinsic permeability of a defect-free membrane.

Membrane Devices

Gas separation modules can be prepared from flat sheets as plate and frame assemblies and spiral-wound elements. Hollow fibres can be fine fibres ($< 1000 \mu\text{m}$ OD) or tubular. In general only fine fibres and spiral-wound elements combine

Figure 19 Membrane technology: breakdown by application.

performance and cost parameters providing economic viability. The benefits of the spiral-wound configuration include ease of fabrication and low pressure drop but manufacturing costs are high and the membrane surface area to module volume ratio is low ($\approx 700 \text{ m}^2 \text{ m}^{-3}$), leading to larger, heavier systems. Hollow fibre modules can achieve very high surface area/volume ratio ($> 5000 \text{ m}^2 \text{ m}^{-3}$) and provide a higher degree of countercurrent flow but are more difficult to fabricate and can have high pressure drop.

Flat Sheets and Spiral-Wound Elements

A schematic representation of a flat-sheet asymmetric casting device is shown in **Figure 15**. Flat-sheet membranes are typically produced on a nonwoven cloth which provides support for the nascent membrane. These nonwoven cloths are commercially available on large rolls of 24–48 inches. A thin liquid film of dope solution is metered by a doctor blade onto the nonwoven cloth while the fabric ro-

tates around a stainless steel roller. The nascent membrane is quenched in the gel tank, washed and collected on a take-up roller. A generic spiral-wound element is shown in **Figure 16**. The simplest configuration consists of a central collection pipe around which is wound and glued an envelope of flat-sheet membrane. The envelope contains the membrane and feed and permeate spacer channels. The spacer material is an extremely porous, inert material. Feed gas flows parallel to the permeate pipe; permeating gas flows into the permeate spacer and is collected in the pipe. Higher membrane areas can be achieved using the multileaved method in which two to four sheets of membrane are wrapped simultaneously.

Hollow Fibres

A second asymmetric membrane geometry is that of a hollow fibre. The ultrathin skin is present on the external surface of the fibre. Like the flat sheet, the wall of the fibre is microporous and offers low resistance to gas flow. The permeating gases collect in the bore or lumen of the fibre. A generic hollow-fibre spinning device is shown in **Figure 17**. The apparatus contains a dope reservoir, a bore fluid reservoir, pumps, coagulation baths, wash baths and a take-up winder. The dope solution and bore fluid are co-extruded through a die, resulting in a sheath of polymer around the bore fluid (typically water). This nascent fibre is then coagulated, washed and dried. Hollow-fibre devices contain thousands, even hundreds of thousands, of individual fibres within a single pressure housing (**Figure 18**). The feed gas is usually fed to the outside of the fibre (shell side) although some processes route the feed gas through the fibre

Table 4 Selected membrane applications

Category	Range of operation	Application	Gases separated
Hydrogen recovery	95% H_2 <5 MMSCFD	Ammonia synthesis purge gas Syngas ratio adjustment Hydrotreater off gas	H_2/N_2 , Ar H_2/CO

bore, especially when well-defined flow characteristics are required.

Applications

The first successful commercial activity in gas separation by membranes began in 1977 with the introduction of the Prism[®] membrane system by Monsanto (now Air Products and Chemicals, Inc.), to recover H₂ from ammonia synthesis plant purge gas. Installed membrane capacity in 1977 was only 5 MMSCFD (million standard cubic feet per day) and grew to over 3500 MMSCFD by 1996. Approximately two-thirds of current installed membrane capacity is used for H₂ separation, which includes ammonia purge gas, refinery and petrochemical applications (Figure 19). Significant growth is expected for N₂ and CO₂ separations. While the specifics will vary according to application, a generic membrane system will include a compressor if the source gas is not available at pressure and pretreatment to remove condensable, corrosive or reactive components. The partial listing of applications (Table 4) represents established uses for gas separations. Expanding the slate continues to be a focus of membrane manufacturers and research institutes.

Future Trends

The concurrent need for high performance polymers and low cost membranes has resulted in research into hybrid polymer systems and improved manufacturing processes. Four areas currently being explored are:

1. *Polymer blends*: A hybrid polymer system in which expensive, high performance polymers form a continuous phase in a multipolymer blend.

Examples include Matrimid/Ultem[®] 1000 and aromatic polyimides/polysulfone.

2. *Coextruded composite hollow fibres*: An improved hollow-fibre spinning process in which a forming asymmetric substrate is simultaneously coated with a thin film of separating polymer by employing a die similar to that shown in Figure 20. This is a paradigm shift away from separate substrate fabrication and subsequent coating practices. The co-extrusion processes should lower manufacturing costs and relax price constraints on new high performance polymers.
3. *Organic/inorganic mixed matrix membranes*: A nanocomposite composite is a hybrid in which very small particles of a material with high diffusive selectivity such as a microporous carbon is dispersed with an organic polymer matrix. Such materials combine the high selectivity of the inorganic with the processability of the organic polymer matrix.
4. *Computational methods*: Molecular modelling of gas transport through rubbery polymers has already proven successful. Its application to glassy polymers is significantly more difficult, primarily because of the poorly defined nature of the glassy state, but significant progress has been made in the last several years. As our understanding of gas-polymer and polymer-polymer interactions improves and merges with advancing computer technology, widespread use of molecular dynamics should provide significant insight into gas separation with polymer membranes.

Introduction

The separation of solutes by means of liquid membranes is based on a simple and well-established idea: two completely miscible liquid phases, separated by a third liquid, immiscible with either of them, can exchange solutes, provided there is a difference between their chemical potentials in the two phases and provided the intermediate liquid is able to transport them. In most cases the two miscible liquids, denoted hereafter as donor and acceptor phases, are aqueous solutions and the third (membrane) phase is an organic liquid. The configuration involving two organic solutions separated by an aqueous membrane is less popular.

The growing interest in the recovery and separation of solutes by means of liquid membranes may be related to the advantages of this separation method over the related separation operations – solid membranes and solvent extraction – as well as to the recent development of efficient liquid membrane techniques and contactors.

The main advantage of liquid membranes over polymer ones is the higher flux, owing to the very much higher diffusion coefficients of solutes in liquids than in solids. Moreover, some liquid membrane techniques allow a convective diffusion regime instead of a molecular one, which also increases fluxes. Another advantage of liquid membranes is the availability of a great number of substances which, when added to the liquid membrane phase, increase selectivity.

A liquid-membrane process can be regarded as a combination of extraction and a stripping process, which take place simultaneously in the same device. In solvent extraction, both the extractant amount and the distribution coefficient of the solute play essential roles for process efficiency, whereas in liquid membrane separation the selectivity is controlled by the kinetics of the transport process. In contrast to solvent extraction, in liquid membrane separation the amount of transferred solute is not proportional to the amount of the solvent used, in this case the membrane liquid. The relatively small amount of the latter permits the use of various highly efficient and selective – even expensive – carriers.

Mechanisms of Solute Transfer

Like some of the solid-membrane separation methods, the difference between the chemical potentials of the solute in the donor and acceptor solutions controls the transport of the species. In other words, the concentration difference is the driving force.

There are various mechanisms for the selective transfer of solutes in the considered three-liquid-phase system. They can be divided into two groups: nonfacilitated and facilitated, or carrier-mediated, transfer mechanisms.

In nonfacilitated processes, the membrane phase is the solvent and carrier of the solute. In facilitated processes, the membrane phase is a neutral medium, dissolving a carrier, which reacts with some molecules or ions and selectively transfers them to the acceptor phase. The carrier reacts reversibly with the solute by binding it in the donor solution or at the interface between this solution and the membrane phase; it transports it across the bulk of the membrane, and releases it at the other interface. When the transfer of

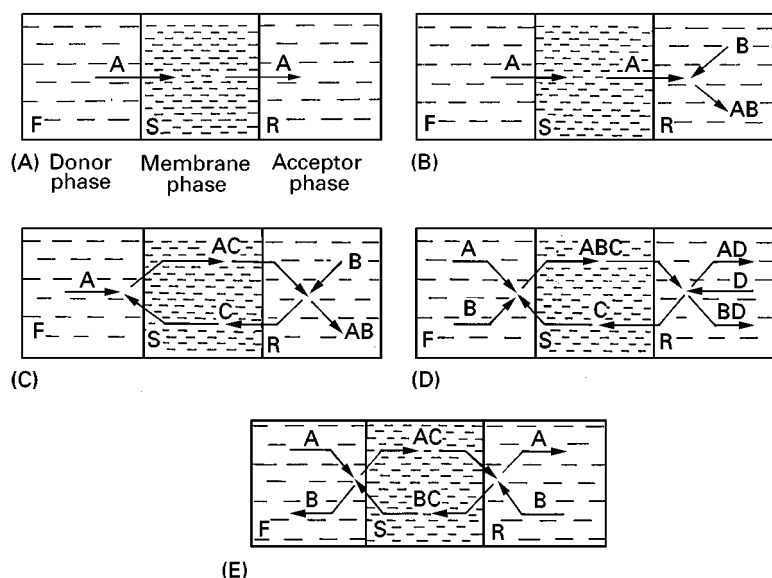

Figure 1 Basic transport mechanisms. (A) Simple nonfacilitated transport; (B) Simple uphill nonfacilitated transport; (C) facilitated uphill transport; (D) facilitated (coupled) co-transport; (E) facilitated (coupled) countertransport. See text for details.

a solute is accompanied by an equivalent transfer of one or more other solutes, it is designated as coupled transport. Depending on the direction of the accompanying transfer, the mechanisms are called co-transport and countertransport. **Figure 1** illustrates the five most popular transport mechanisms: (A) and (B) refer to nonfacilitated mechanisms, while (C)–(E) refer to facilitated mechanisms.

Nonfacilitated Mechanisms

Figure 1A shows the nonfacilitated transport of solute A from the donor solution to the membrane liquid as a result of its solubility and the low concentration in the latter. From this phase, it is transferred to the acceptor phase again for the same reasons. This process continues until the chemical potentials of the solute, i.e. its concentrations in the donor and acceptor solution, are equal. The selectivity of separation of solutes present in the donor solution mainly depends on the difference between their transfer rates, which in turn are related to their solubility in the membrane and, to a lesser extent, on the difference between their diffusion coefficients. This rather simple mechanism is of no practical interest. An example is the separation of aromatic and aliphatic hydrocarbons using water as the membrane phase.

Figure 1B shows a second example of nonfacilitated transport. The process differs from Figure 1A in that the acceptor solution has a component B which is insoluble in the membrane; it reacts irreversibly with solute A that permeates through the membrane. The reaction product AB is insoluble in

the membrane and cannot diffuse back to the donor solution. In some cases an enzyme plays the role of the reagent B, transforming transported solute into products which are insoluble in the membrane. The continuous consumption of A in the acceptor solution maintains its concentration in this phase at a low level, creating a sufficient driving force to transfer the whole amount of A from the donor solution. The solute A in the form of the product AB can reach very high concentrations in the acceptor solution, which is generally of a smaller volume than the donor solution. This transfer, apparently against the concentration gradient, is known as a simple uphill transport and it has a real practical value. A typical example is the transfer of a phenol as a neutral solute which is soluble and thus permeable through the organic membrane phase. The acceptor phase is an alkaline solution that converts the phenol to an ionized salt which is not soluble or permeable through the membrane phase.

Facilitated Transport Mechanisms

In facilitated transport mechanisms the neutral membrane liquid contains an active substance C, which selectively and reversibly reacts with the permeating solute, forming a complex AC (Figure 1C). This complex is formed at the donor interface of the membrane phase and then, due to its concentration gradient, moves to the acceptor solution membrane-phase interface. The complex AC then reacts with a reagent B. As a result of this reaction, A is irreversibly bound by B, while the carrier C is restored and goes back across

the membrane to the feed-membrane interface to bind a new portion of the solute A. Because of this shuttle mechanism, small amounts of the carrier C can transfer large amounts of the solute in the acceptor phase. An example is the recovery of nitric acid from dilute solution using a small amount of the carriers tributylphosphate or trioctylphosphine oxide. The adducts formed are unstable in strongly alkaline media (the acceptor solution), where the acid is neutralized and irreversibly converted into nitrate.

In transport processes shown in Figure 1D, sometimes called facilitated co-transport, the carrier C reversibly forms an intermediate complex not only with the solute A but also with other (one or more) constituents of the donor solution. The complex ABC so formed is transported to the acceptor solution, where it reacts with another additive, D, by forming a more stable compound. The latter, like the reagent D, is insoluble in the membrane liquid. An example of this mechanism is the transport of silver which is selectively recovered from complex polymetallic nitrate solutions. The complex, transferred across the membrane, is formed by a silver cation, a nitrate anion and two molecules of the extractant triisobutylphosphine sulfide, selective for silver. In the acceptor solution, the complex is destroyed by ammonia. The chemical reaction in the acceptor phase yields ammonium nitrate, the stable silver-ammonia complex and the regenerated carrier.

Figure 1E illustrates the third, probably most often used, facilitated transport mechanism, sometimes called facilitated countertransport. In this case, ions, initially present in the donor solution, are substituted

by other ions of the same type, present in a sufficient amount in the acceptor solution. This is actually an ion exchange process in which the ion-exchanging agent, the carrier C, transports in one direction one type of ion and in the opposite an equivalent amount of substituent. A typical example for this transfer is the recovery of some divalent metal cations, e.g. Cu^{2+} , from neutral or slightly acidic aqueous solutions by means of oleophilic chelating oximes. The latter transfers the metal ions to the strongly acidic acceptor solution and returns protons according to the scheme:

The equilibrium conditions at the two interfaces, controlled by the pH values of the aqueous phases, are chosen so that the metal-organic complex is the stable species at the donor-membrane interface, while free cations exist at the membrane-acceptor interface. This type of process is of great significance for hydrometallurgy and for the removal of heavy metals from industrial effluents.

These five types of transfer mechanisms do not exhaust all possible schemes for the selective recovery and separation of solutes by means of liquid membranes. Liquid membrane processes have been developed during the last few years on the basis of various transport and reaction mechanisms, including redox reactions. For example, the selective transfer of metals may result from the different solubility of their ions at various oxidation states. Of equal interest are some enzymatic reactions, both in the bulk of the

membrane and in the bulk of the acceptor solution. The reader may find further information in the Further Reading section.

Liquid Membrane Techniques

The main reason for the limited large scale application of liquid membrane processes is the lack of efficient equipment providing simultaneously large contact areas and high fluxes between the phases without deterioration of the membrane over time causing intermixing of the donor and acceptor phases. The realization of stable membranes is an extremely difficult task.

In general, liquid membrane techniques can be divided into two groups: techniques in which there is no dispersion of phases and techniques with at least one dispersed phase. The first group includes bulk liquid membranes and the supported liquid membranes, as well as some recent techniques combining elements from both techniques. The second group is mainly represented by the emulsion liquid membrane technique.

Methods Without Phase Dispersion

Simple bulk liquid membranes Several simple contact devices designed for studies of liquid-membrane processes are shown in Figure 2. In all, there is a common compartment for the membrane liquid. The other contactor space is divided into two compartments, one for the donor solution and the other for the acceptor solution. The interface between the membrane liquid and the other two solutions is free (A, B) or immobilized (C, D) by a solid porous membrane. The first device (A) is known as the Schulmann bridge. Devices of the type shown in Figure 1A and B are limited to laboratory experiments, but the con-

tactors shown in Figure 2C and D find a broader application. In these devices, the membrane liquid permeates a porous membrane, which separates the donor and the acceptor solutions. In modification (D), a cylinder with an attached porous barrier rotates and stirs the donor and acceptor phases, reducing or eliminating the mass transfer resistances in these two phases. The type of device depends on whether the membrane liquid is heavier or lighter than the other two solutions.

Supported liquid membranes The laboratory contactor shown in Figure 2C is the prototype of supported liquid membrane contactors. In these devices the membrane liquid fills the pores of a 25–100 μm thick porous membrane containing pores 0.01–10 μm in diameter. The membrane is usually made of polypropylene, polysulfone or another oleophilic polymer.

Although the membrane is quite thin, the fluxes across it are very low as a result of the total immobilization of the membrane liquid in the pores, reduced free section and pore tortuosity. This is overcome by the use of large surface area modules such as the spirally wound (Figure 3) or containing bundles of tiny porous hollow fibres, as shown in Figure 4. Hollow fibre membrane modules containing fibres with diameter of 0.2–1 mm can achieve interface areas of

Figure 4 Hollow fibre supported liquid membrane module. R, Acceptor solution; F, donor solution; S, membrane liquid.

2000–10 000 m²/m³. In such modules, one of the aqueous phases flows in the lumen of the hollow fibres, while the other flows outside the fibres and the pores of the fibre walls are filled with the membrane liquid.

The insignificant amount of membrane liquid required in these modules (10 cm³ per 1 m² interface), often pointed out as a major advantage, is actually the chief drawback of supported liquid membrane contactors, causing their operational instability and short life. The life of the expensive modules is shortened by the inevitable solubility of the membrane liquid in the donor and acceptor phases, by its washing out or by emulsification caused by the pressure difference on both sides of the membrane, the lateral shear force, and the change of support wettability with time. In spite of numerous design improvements, e.g. periodic or continuous reimpregnation of the membrane and partial or total gelation of the membrane liquid, this technique has not been used in industrial applications.

This instability forced researchers as early as in the 1980s to look for other solutions. The combination of this technique with stable bulk liquid membranes yielded the bulk-supported liquid membranes.

Flowing liquid membranes and contained liquid membranes In these two variants of the bulk-supported liquid membrane group, as well as in numerous subsequent modifications, the membrane liquid not only fills the pores of two closely spaced porous supports separating the donor and acceptor phase, but also the space between them, as shown in Figures 5 and 6. Figure 5 shows a device introduced by Teramoto *et al.*, called the flowing liquid membrane: the spirally wound module contains one additional layer and one additional porous barrier (Figure 5) in comparison with the analogous supported liquid membrane module, shown in Figure 3. Between the two, separated by porous support spacers, flows the membrane liquid, which also fills the pores of the support which are preferentially wetted by it.

In contained liquid membranes, a technique proposed by Sirkar *et al.* in the late 1980s, the donor phase flows in the lumen of a part of the capillaries, while the acceptor phase flows in the lumen of the rest of them. As Figure 6 shows, the membrane liquid filling the space outside the hollow fibres can also be set in motion. When the hollow fibre material is wetted by the membrane liquid, the pores are filled with it. In the reverse case, they are filled with the other two phases. The module shown in Figure 6, in which the inlets and the outlets of the feed and acceptor phases are located in one end of the module case,

permits free elongation of the fibre package caused by the swelled membrane liquid.

The latter two membrane techniques provide significantly longer life of the contactors, as the inevitable losses of membrane fluid are compensated by the larger liquid volume. However, fluxes are lower because of higher mass transfer resistance due to the second porous support filled with immobilized liquid and the two additional diffusion boundary layers in the same phase. This drawback is, however, offset by the longer membrane life.

A further modification of the contained liquid membrane technique is the separation of the two hollow fibre packages in two modules – one where the donor liquid exchanges solutes with the membrane liquid and a second where the membrane

liquid contacts with the acceptor liquid. The membrane liquid circulates between the two devices. This technique, bearing the name two-module hollow fibre supported liquid membranes, differs little from the arrangement in a conventional extraction-stripping unit operation.

Liquid film pertraction The technique known as liquid film pertraction attempts to combine the advantages of bulk liquid membrane and supported liquid membrane. In the process all three liquids are in motion and the interfaces between the phase pairs are not immobilized, so that the transport rate in all stages of the transfer process is controlled by convective transport instead of the much slower molecular diffusion.

Two devices utilizing this technique are schematically presented in Figure 7. In the first one, called the

falling film pertraction, shown in Figure 7A, the donor and acceptor solutions flow down the surface of alternating vertical supports. The spaces between the opposite supports, covered by films of donor and acceptor liquids, respectively, are filled with the membrane phase, flowing countercurrent to the other two. By independent control of the flow rates of the feed and acceptor phases, a significant solute accumulation in the acceptor solution can be achieved.

The second technique, rotating film pertraction uses a package of rotating horizontal discs wetted only by the feed and receptor phases. This rotation generates an intensive transfer regime in all three liquids. As Figure 7B shows, the discs, alternately mounted on a shaft, are partially immersed in the corresponding wetting solutions and on rotation form mobile films which directly contact with the membrane liquid filling the spaces between the discs.

Figure 8 Separation by emulsion liquid membranes. 1, Emulsion preparation (step 1); 2, feed treatment with the emulsion (step 2); 3, break-up of enriched emulsion (step 3). R, Acceptor solution; F, donor solution; S, membrane liquid.

The advantages of these two techniques consist in the considerably larger fluxes per unit interface and in their practically unlimited life. However, the rather low ratio between the contact interface and the bulk of the solution neutralizes, the first advantage.

Methods with Phase Dispersion

Emulsion (surfactant) liquid membranes Emulsion liquid membranes were first described in 1971 by Li in a paper dealing with the separation of aromatic and aliphatic hydrocarbons by stabilized dispersion of three liquids: the above-mentioned mixture, water and an inert hydrocarbon as a recipient phase. This technique, known as emulsion (or surfactant) liquid membranes, was the first pertraction technique developed to industrial scale.

As the name implies, the three-phase system is stabilized by an emulsifier, added to the membrane liquid, in some cases its concentration in the membrane liquid reaches 5% or more. The acceptor solution is dispersed as fine (2–20 μm) droplets in the membrane phase. The thick emulsion, stabilized by the emulsifier, is dispersed in its turn in the donor solution as globules of 1–2 mm diameter and the resulting dispersion is intensely stirred for several minutes. During this contact time, the solutes, which are more soluble in the membrane phase, are transferred from the donor phase to the intermediate phase and from there to the encapsulated acceptor solution. This transfer is very fast due to the large contact areas. After termination of the second (main) process step and dispersion settling, the enriched emulsion is separated and subjected to chemical, thermal or, most often, high voltage electrocoagulation, which breaks the emulsion into two phases. The separated membrane liquid phase is fed back for a new cycle of the process and the enriched acceptor solution phase is subjected to further treatment. The scheme in Figure 8 illustrates this three-stage batch process which in some modifications is carried out as a continuous process. In this process, the recovery efficiency and the separation selectivity are controlled by the transfer kinetics, i.e. by the difference in the transfer rates of the individual solutes. As these rates depend on a great number of factors, for each case there is a specific optimum contact time, which can only be determined experimentally. A shorter than optimum contact time results in a lower solute recovery, while a longer contact time reduces selectivity and recovery efficiency. If the emulsion is too stable, this causes problems related to its break-up in the third process step. Irrespective of these drawbacks, the emulsion liquid membrane technique is most often investigated and practically applied.

Figure 9 Two-compartment pulsating column. Applied pulsations, D, exchange the membrane liquid S between central and annular compartments across the porous wall. R, Acceptor solution; F, donor solution; S, membrane liquid.

Other techniques with phase dispersion In addition to the disadvantages listed above, the added emulsifier contaminates both the donor and acceptor phases, as in some cases its solubility in these phases exceeds that of the membrane liquid itself or of the carrier added. To avoid using surface active substances, other techniques with phase dispersion were recently proposed, two of which are illustrated in Figures 9 and 10.

Co-axially placed in the vertical tube is a second tube of porous hydrophobic material, e.g. porous polypropylene. As shown in Figure 9, both internal and annular spaces are filled with the membrane liquid which, under laterally applied pulsations, partially goes from one space to the other and back. The

Figure 10 Combination of hollow fibre supported liquid membranes with the emulsion technique in which a nonstabilized phase R dispersed in phase S emulsion flows inside the hollow fibres.

two aqueous feed and acceptor phases are fed into the top of the central and annular space, respectively, as droplets of about 1 mm diameter. The porous filter tube does not allow intermixing of the droplets of the two aqueous phases. The aqueous droplets should be small enough to guarantee sufficient residence time of the corresponding phase in the contractor, but not too small that it penetrates into the other compartment.

The second arrangement avoiding the use of surface active substances is shown in Figure 10. The technique is a combination of hollow fibre and emulsion liquid membrane techniques without using an emulsifier for dispersion stabilization. The acceptor/membrane-phase emulsion flows in the lumen of porous capillaries wetted by the membrane liquid, filling their pores. Evidently, no intense mass transfer is possible with this technique, irrespective of the continuous wash-out of the membrane liquid by the acceptor solution dispersed in it. This drawback is, however, again compensated for by the great number of hollow fibres used and by the recirculation of the intracapillary dispersion.

Application Areas

The liquid membrane processes described above are in principle highly efficient chemical pumps selectively separating and concentrating valuable solutes. These processes have potential applications in a num-

ber of industrial areas, e.g. hydrometallurgy, electroplating and galvanic technologies, chemical and pharmaceutical industries. One of the most promising applications is in biotechnology, where pertraction, can be integrated with the basic bioprocess in order to increase process efficiency.

A very attractive feature of pertraction processes is their low investment, and in particular, their operational costs. Being a membrane operation, the separation does not involve phase transitions and therefore power consumption is very low. However, unlike solid membrane separations, the costs of lost membrane liquid and the purification of treated solutions sometimes required additionally contribute to the process costs.

The Further Reading section lists titles containing more information on various pertraction systems studied in the last 25 years.

Membrane processes are particularly well suited to the separation and purification of biological molecules since they operate at relatively low temperatures and pressures and involve no phase changes or chemical additives. Thus, these processes cause minimal denaturation, deactivation and/or degradation of highly labile biological cells or macromolecules. Although essentially all membrane processes (Figure 1) have been used for bioseparations, the greatest interest has been in the application of the pressure-driven processes of ultrafiltration (UF) and microfiltration (MF). Ultrafiltration membranes have pore sizes between 1 and 50 nm and are used for protein concentration, buffer exchange, desalting, clarification of antibiotics and virus clearance. There is also growing interest in the use of ultrafiltration for protein purification using high performance tangential flow filtration (HPTFF). Microfiltration membranes have a pore size between 0.05 and 10 μm and are thus used

for initial clarification of protein solutions, cell harvesting and sterile filtration. In addition, ultrafiltration and microfiltration of blood are used for the treatment of a variety of metabolic and immunological disorders.

The development of membrane processes for bioseparations is very similar to the design of membrane systems for nonbiological applications. However, there are some important differences including:

1. increased concerns about deactivation or denaturation of biological molecules and cells
2. very high value (on a per unit mass basis) of most biological products (particularly recombinant therapeutic proteins)
3. tendency of biological macromolecules and cells to cause significant fouling of both ultrafiltration and microfiltration membranes
4. critical importance of validation and integrity testing in bioprocessing applications

This article provides a brief review of the historical development of membrane systems for bioseparations. This is followed by a general discussion of the

underlying principles governing the design of ultrafiltration and microfiltration systems, with particular emphasis on those factors that are most significant for bioseparations. The reader is referred to the Encyclopedia articles on Membrane Separations – Microfiltration and Membrane Separations – Ultrafiltration for more detailed discussions of these membrane technologies.

Historical Development

The first mention of the process now known as ultrafiltration appears to have been in an 1856 study by Schmidt on the filtration of protein and gum arabic through animal membranes. Thus, the idea of using ultrafiltration for bioseparations dates back well over 100 years. Bechhold coined the term ultrafiltration in 1906 during a systematic study of the behaviour of different pore size collodion membranes made by impregnating filter paper with acetic acid and cellulose nitrate. Zsigmondy obtained one of the first patents in membrane technology in 1922 for the preparation of flat collodion membranes from ether-alcohol solutions. The first efforts to develop microporous membranes in the USA were motivated by the need for rapid detection and analysis of biological warfare agents. This technology was subsequently transferred to the Lovell Chemical Company, which ultimately led to the establishment of Millipore Corporation.

The early historical development of ultrafiltration and microfiltration is described in an excellent review article by Ferry in 1936. The primary applications of membrane technology in the early 1900s were for a variety of biological, analytical and bacteriological assays. Ferry also described the use of membranes for enzyme concentration, analysis of bacteriophages and viruses, blood ultrafiltration to prepare cell- and protein-free ultrafiltrates, sterile filtration of biological solutions and the partial separation of albumin from globulins in blood serum. All of these bioseparations remain areas of active commercial interest even today.

Although many of the potential uses of membrane systems in bioprocessing were identified well over 60 years ago, the collodion (cellulose nitrate) membranes available at that time had inadequate chemical, mechanical and mass transport properties for the effective use of ultrafiltration on an industrial scale. The key breakthrough was the development of the asymmetric cellulose acetate reverse osmosis membrane by Loeb and Sourirajan in the early 1960s and the subsequent extension of this technique to produce asymmetric ultrafiltration membranes. These asymmetric membranes have a very thin skin (approxim-

ately 0.5 μm thick), which provides the membrane with its selectivity, and a more macroporous substructure, which provides the required mechanical and structural integrity. The thin skin results in much higher permeation rates than are obtainable with homogeneous membranes, significantly reducing the required membrane area and/or process time.

Ultrafiltration is now used throughout the downstream separation process for the purification of therapeutic recombinant proteins, blood components, natural protein products and industrial enzymes. Specific applications include protein concentration (i.e. volume reduction), desalting and buffer exchange, all of which are used to condition the product prior to, or immediately after, other separation processes or as part of the final product formulation. In addition, ultrafiltration is used extensively for the clarification of antibiotics, amino acids and other small biological molecules. Recent work has demonstrated that ultrafiltration membranes are also capable of effecting protein–protein separations using a process known as HPTFF. Microfiltration membranes are used for cell harvesting, initial clarification of cell culture media and fermentation broths, and for sterile filtration of products that are directly added to pre-sterilized containers. Sterile filters are also used to remove bacteria and particles from feedstock solutions and to reduce the overall bioburden in processes where the product will be subjected to a terminal sterilization step. Virus removal membranes are used as part of the overall viral clearance required for the production of therapeutic proteins and blood products. Virus filters can also provide a protective barrier for bioreactors through the filtration of media and buffer solutions.

Ultrafiltration and Microfiltration Principles

Membrane Selection

Membrane selection should start with the choice of a high quality vendor since robustness, reliability and reproducibility of manufacturing operations are of paramount importance in most bioprocessing applications. Consistent membrane and device characteristics can be as important to product quality, yield and economics as the inherent differences between various membranes and devices. Cellulosic membranes are attractive for many bioprocessing applications because of their low protein adsorption and low fouling characteristics. Synthetic polymers (e.g. polysulfone and polyvinylidene fluoride) are also attractive due to their greater chemical and mechanical stability. These polymers are often surface-treated to

render them more hydrophilic to reduce protein adsorption and fouling. Membranes used for sterile filtration must be steam-sterilizable, have minimal particle shedding, low extractables and must pass United States Pharmacopoeia (USP) Class VI toxicity testing.

Most manufacturers rate ultrafiltration membranes by their nominal molecular weight cutoff, which is defined as the molecular weight of a solute with a particular retention coefficient:

$$R = 1 - C_{\text{filtrate}}/C_{\text{feed}} \quad [1]$$

where C_{filtrate} and C_{feed} are the solute concentrations in the filtrate solution and feed stream, respectively. Data are typically obtained with a range of model proteins or with polydisperse dextrans. Unfortunately, the procedures used for assigning molecular weight cutoffs, including the choice of solutes, the specific buffer and flow conditions, and the chosen retention value (usually $R = 0.9$) vary widely throughout the industry. In addition, ultrafiltration systems used in bioprocessing generally require protein retention of at least 99%, and often as high as 99.9%, to minimize loss of high value products through the membrane. Data obtained with solutes having $R = 0.9$ are often of little value in determining whether a given membrane can provide these high levels of protein retention due to differences in the details of the pore size distributions.

Microfiltration membranes are typically rated by their pore size or their particle retention characteristics using the log reduction value (LRV), defined as the logarithm (base 10) of the ratio of the particle, cell or virus concentration in the feed to that in the filtrate solution. Sterilizing-grade ($0.2 \mu\text{m}$ pore size) filters are currently defined by the Health Industry Manufacturing Association (HIMA) as a filter which produces a sterile filtrate when challenged by 10^7 colony-forming units of *Brevundimonas diminuta* (formerly classified as *Pseudomonas diminuta*) per cm^2 of membrane area. This challenge uses the smallest bacteria at a concentration that exposes essentially every pore to the microorganisms. Sterile filters are often thought of as operating via a purely size-based (siev-

ing) mechanism, although bacteria can also be removed by adsorption on to the membrane surface.

The chemical compatibility of the membrane needs to be verified with the feed, regeneration chemicals and storage solutions. Sodium hypochlorite (NaOCl) is used most extensively for chemical disinfection of membrane systems in bioprocessing applications. Many membrane systems are designed for steam-in-place (SIP) sterilization, with the entire unit exposed to flowing steam as part of the completely assembled filtration system. Minimum requirements for an effective steam sterilization are 15 min exposure to steam at 121°C and 1 atm pressure. Polysulfone membranes tend to have broader chemical and thermal stability than cellulosic membranes but also require harsher chemical treatment for regeneration due to their greater fouling characteristics. Inorganic (ceramic) membranes have the greatest chemical compatibility, but they are much more expensive than polymeric membranes. The mechanical strength of the membrane is important since reverse-pressure spikes can cause membrane delamination and catastrophic yield loss.

Module Design

Dead-end, or normal-flow, filtration (Figure 2A) is used primarily for laboratory-scale separations and for systems in which the retained species are present at very low concentration. For example, dead-end microfiltration cartridges are used extensively for sterile filtration since the retained bacteria are present at very low concentration. Similar modules can be employed for virus removal applications. Almost all large scale commercial ultrafiltration devices use tangential flow filtration, also referred to as a cross-flow configuration, in which the feed flow is parallel to the membrane and thus perpendicular to the filtrate flow (Figure 2B). This allows retained species to be swept along the membrane surface and out of the device exit, significantly increasing the process flux compared to that obtained with dead-end operation.

A number of tangential flow modules have been developed for ultrafiltration and microfiltration

Figure 2 Comparison of (A) dead-end and (B) cross-flow configurations.

Table 1 Comparison of different module configurations

Module configuration	Channel spacing (cm)	Packing density ($\text{m}^2 \text{m}^{-3}$)	Energy costs (pumping)	Particulate plugging	Ease of cleaning
Flat sheet	0.03–0.1	300	Moderate	Moderate	Good
Hollow fibre	0.02–0.25	1200	Low	High	Fair
Tubular	1.0–2.5	60	High	Low	Excellent
Spiral wound	0.03–0.1	600	Low	Very high	Poor to fair

processes, differing primarily in the size and shape of the feed and filtrate flow channels. **Table 1** provides a general summary of the physical characteristics of the most common modules. Detailed descriptions of these modules are available elsewhere.

The small channel spacing in flat-sheet, hollow-fibre and spiral-wound modules provides high membrane-packing densities. In addition, these modules have low hold-up volumes, which facilitates the recovery of high value products. The screens used to define the flow path in spiral-wound modules and many flat-sheet cassettes are susceptible to particle plugging and this may make cleaning more difficult. Hollow-fibre membranes are self-supporting, so they can often be cleaned by simple backflushing. The large-bore tubular membranes can be cleaned by both physical and chemical methods. However, these modules operate in the turbulent flow regime which can cause cell lysis, protein denaturation or aggregation. A variety of enhanced mass transfer modules which exploit flow instabilities have also been developed for bioprocessing applications. Rotating cylinder modules which induce Taylor vortices have very high mass transfer rates, although there are concerns about the moving parts. Another attractive approach is to use helically coiled hollow fibres wrapped around a central core to induce Dean vortices.

Process Configurations

Protein concentration can be carried out using either batch or fed-batch operation (**Figure 3**). In a batch process, the entire feed volume is contained within the recycle tank. Tank design is critically important to ensure adequate mixing while avoiding air entrainment and excessive foaming. Batch operation uses a minimum of hardware and allows simple manual or automatic control. The flux rates are also higher in batch processes since the bulk concentration follows a more dilute path in going from initial to final concentration. Disadvantages of the batch configuration include less flexibility in using the same system for multiple processes, greater difficulty in designing a well-mixed system, and difficulties in obtaining high concentration factors.

The fed-batch configuration utilizes an additional tank to feed into the recycle tank (**Figure 3**). Fed-batch configurations are commonly used to obtain high concentration factors and to provide well-mixed, low-hold-up, retentate reservoirs. These systems also provide flexibility for use in multiple processes. The disadvantages of the fed-batch system include greater process time and greater number of passes of the retentate through the pumps and valves in the recycle line. The latter can lead to excessive cell lysis, protein denaturation or aggregation.

Diafiltration is commonly used for buffer exchange (for products in the retentate) and to enhance yield (for products in the filtrate). The diafiltration system looks similar to the fed-batch configuration shown in **Figure 3** except that the feed tank contains a buffer solution which is added to the recycle tank. The most common approach is constant retentate volume diafiltration in which the buffer is added at the same rate as filtrate removed.

The yield and purification obtained in ultrafiltration and microfiltration processes can be evaluated from simple mass balances on the product and impurity assuming constant rejection coefficients. The final product concentration (C_F) at the end of a batch concentration process is given as:

$$\left(\frac{C_F}{C_0}\right) = \left(\frac{V_0}{V_F}\right)^{1-S} \quad [2]$$

where V_F is the final retentate volume, V_0 is the initial retentate volume and S is the product sieving coefficient (equal to one minus the rejection coefficient). The analogous expression for a fed-batch process is:

$$\frac{C_F}{C_0} = \frac{1}{S} + \left(1 - \frac{1}{S}\right) \exp\left[-S\left(\frac{V_0}{V_F} - 1\right)\right] \quad [3]$$

The final concentration after a constant retentate volume diafiltration is:

$$\frac{C_F}{C_0} = \exp(-SN) \quad [4]$$

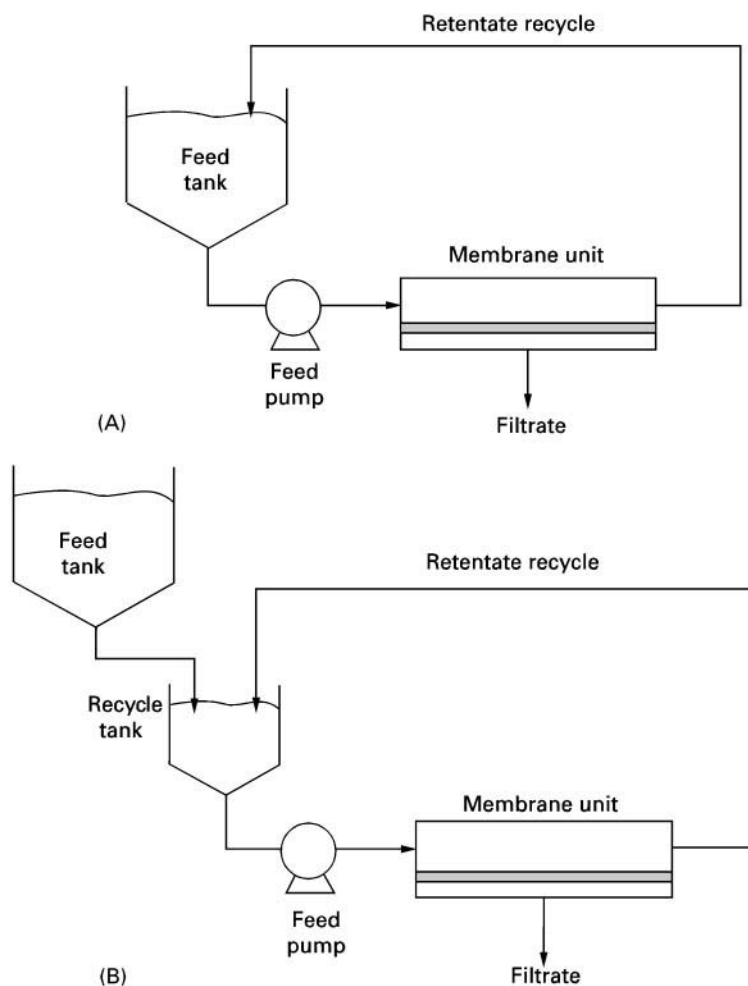

Figure 3 Comparison of (A) batch and (B) fed-batch processes for protein concentration.

where the number of diavolumes (N) is given by:

$$N = V_D/V \quad [5]$$

where V_D is the diafiltration buffer volume. Even very small sieving coefficients may result in substantial product loss when a large number of diavolumes are required in diafiltration processes. For example, a diafiltration process with a product sieving coefficient of $S = 0.01$ will result in a 10% product loss during a 10 diavolume buffer exchange.

Concentration Polarization

One of the critical factors determining the overall performance of tangential flow filtration devices is the rate of solute/particle transport in the bulk solution adjacent to the membrane. The filtrate flow causes an accumulation of partially (or completely) retained components at the upstream surface of the membrane, a phenomenon referred to as concentration

polarization. The concentration thus varies from its maximum value at the membrane surface (C_w) to its bulk value (C_b) over the thickness of the concentration boundary layer (δ). Most analyses of concentration polarization have employed the simple stagnant film model in which:

$$J = k \ln \left(\frac{C_w - C_f}{C_b - C_f} \right) \quad [6]$$

where J is the filtrate flux (typically in $\text{L m}^{-2} \text{h}^{-1}$) and k is the solute mass transfer coefficient in the particular membrane device. The accumulation of particles/solutes at the membrane surface increases the overall resistance to filtrate flow through the formation of a particle cake or gel layer and it can reduce the effective pressure driving force through the osmotic pressure of the retained solutes. At high transmembrane pressures, the wall concentration approaches a maximum value determined by the close-packed concentration of the particles or cells, the

protein solubility limit or the concentration at which the osmotic pressure of the retained solutes is essentially equal to the applied transmembrane pressure. The net result is that the flux attains a nearly constant pressure-independent value that increases with decreasing bulk concentration and increasing feed flow rate. The dependence on feed flow rate is determined by the module characteristics: approximately $1/3$ power for laminar flow in hollow fibres and open channels, $1/2$ power for screened channels, and 0.8 power for turbulent flow in tubular modules. The dependence on feed flow rate for cellular suspensions is typically greater than that for protein solutions due to shear-induced particle diffusion and inertial lift effects.

Process Control

Ultrafiltration and microfiltration processes have traditionally been performed at constant transmembrane pressure. Constant-pressure processes are very simple to control. The feed rate is ramped up to the set point and the retentate valve is then partially closed to obtain the desired transmembrane pressure. The transmembrane pressure should be gradually increased to minimize fouling. In some applications it may not be possible to maintain constant transmembrane pressure without severe reductions in filtrate flux over the course of the process due to membrane fouling. This is particularly true for cell microfiltration where the high initial flux leads to very rapid deposition of cells and cell debris on the membrane surface. Several studies have shown that higher overall throughput can often be obtained in these applications by operating at constant filtrate flux. The flux is controlled by regulating the retentate pressure control valve or by using a pump on the filtrate line.

A third method of process control that is very attractive for bioprocessing applications is to vary the filtrate flux so that the wall concentration of retained species (evaluated from eqn [6]) remains constant during the process. Control is performed using a proportional-integral-derivative (PID) loop that measures flux and controls the transmembrane pressure or filtrate flow rate to maintain a constant wall concentration throughout the process. The benefits of constant C_w control are that product yield is maximized, product quality is ensured, membrane area is minimized and process time is consistent and independent of variations in membrane permeability.

High Performance Tangential Flow Filtration

Ultrafiltration and microfiltration have traditionally been limited to separating species that differ in size by

at least 10-fold. In contrast, HPTFF enables the separation of solutes without limit to their relative size. HPTFF is able to obtain the high selectivity required for effective protein purification by exploiting several recent developments. Firstly, HPTFF is operated in the pressure-dependent regime, with the filtrate flux and device fluid mechanics chosen to minimize fouling and exploit the effects of concentration polarization. Since optimal separation in HPTFF is obtained at a specific filtrate flux, the membrane module should be designed to maintain a nearly uniform flux and transmembrane pressure throughout the module. This can be done using a co-current filtrate flow to balance the feed-side pressure drop through the module. Secondly, the buffer pH and ionic strength are adjusted to maximize differences in the effective volume of the different species. The effective volume of a charged protein (as determined by size exclusion chromatography) accounts for the presence of the diffuse electrical double layer surrounding the protein. Protein transmission through the membrane can be reduced by increasing the effective protein volume, e.g. by increasing the net protein charge (by adjusting the pH) or by increasing the double-layer thickness (by reducing the solution ionic strength). Thirdly, the electrical charge of the membrane is chosen to increase the electrostatic exclusion of all species with like charge. Thus, a positively charged membrane will provide much greater rejection of a positively charged protein than will a negatively charged membrane of the same pore size. Fourthly, protein separations in HPTFF are accomplished using a diafiltration mode to wash the impurity (or product) out of the retentate. The diafiltration maintains an appropriate protein concentration in the retentate throughout the separation, and it allows one to obtain purification factors for products collected in the retentate that are much greater than the membrane selectivity due to the continual removal of impurities in the filtrate.

Although HPTFF is still a new membrane technology, a number of recent studies have clearly demonstrated the potential of this separation technique. Several of these results are summarized in Table 2. Purification factors for the separation of bovine serum albumin (BSA) from an antigen-binding fragment (Fab) were greater than 800-fold with either protein collected in the retentate depending upon the choice of solution pH and membrane surface charge. BSA and haemoglobin have essentially identical molecular weight but different surface charge characteristics. In this case, operation at pH 7 caused a strong electrostatic exclusion of the negatively charged BSA from the negatively charged membrane. The separation of BSA monomer and dimer occurs primarily because of the difference in protein size, with the

Table 2 Purification factors and yields for HPTFF processes^a

Product (MW)	Impurity (MW)	Purification factor	Yield
BSA (68 000)	Fab (45 000)	990	94%
Fab (45 000)	BSA (68 000)	830	69%
BSA (68 000)	Hb (67 000)	100	68%
IgG (155 000)	BSA (69 000)	30	84%
BSA (68 000)	BSA dimer (136 000)	9	86%

^aBSA, Bovine serum albumin; Fab, antigen-binding fragment from recombinant DNA antibody; Hb, bovine haemoglobin; IgG, human immunoglobulin.

smaller monomer collected in the filtrate. However, electrostatic interactions are also important in this system due to the combined effects of size and charge on protein transmission and to possible differences in the charge-pH profiles for the monomer and dimer.

Validation and Integrity Testing

Membrane systems used in bioprocessing applications need to be validated to demonstrate consistent purification and yield with minimal alteration in the properties of the product. Food and Drug Administration regulations provide specific guidelines for validation of sterile filters and virus removal membranes. Validation should always be performed at the same pH, ionic strength and chemical environment as used in the actual process to ensure equivalent physical and chemical characteristics of the product and impurities. Viral clearance studies are typically performed by spiking high titre infectious viruses (with different physical characteristics) into scaled-down production systems.

Integrity testing is critical for all sterile and viral filters to ensure that the system operates at the required level of performance. Integrity tests should be performed both prior to, and immediately after, the actual process wherever possible. Integrity tests performed prior to filtration must not affect the sterility of the connections downstream of the filter. The real test for the sterile filter would be to challenge with *B. diminuta*, but the filter could not be used after this test. Thus, a number of surrogate nondestructive integrity tests have been developed. The industry standards are forward flow, pressure decay and bubble point. Each of these tests is based on the displacement of a fluid from the pores by a second fluid (or gas), with the rate of displacement providing a measure of the membrane pore size characteristics. The gas or intrusion liquid expels the wetting liquid out of the pore when the feed pressure exceeds the capillary force within the pore. The bubble point is defined as

the pressure at which the pore is first intruded by the gas. The bubble point for sterilizing grade filters can be correlated to the LRV of *B. diminuta*. Filters with water bubble points of 55 psi or greater typically yield the necessary LRV to be qualified as sterilizing-grade filters. In the forward flow test, one measures the total gas flow rate through the wetted membrane at a fixed pressure. High flow rates indicate the presence of pressure-driven flow through gas-intruded (large) pores. The pressure decay test is performed in a similar fashion, with the gas flow calculated from the rate of pressure decay. A variety of automated integrity test instruments have been developed by the different membrane manufacturers.

Bubble point tests with water-wetted membranes cannot be used to verify virus filter performance since the bubble points for these small pore size membranes would exceed the membrane pressure limits. Air diffusion and bubble point tests can be performed on these membranes using wetting fluids having lower surface tension (e.g. isopropyl alcohol). Liquid intrusion tests using two immiscible fluids (e.g. solutions of a sulfate salt and polyethyleneglycol) have been developed as integrity tests for virus filters and HPTFF membranes.

Summary

Membrane processes should continue to be of critical importance in bioprocessing applications, facilitating the cost-effective production of a wide range of biological products. Ultrafiltration has become the primary means for protein concentration and buffer exchange in the production of therapeutic proteins and industrial enzymes. Sterile filtration is used throughout the bioprocessing industry, and viral filtration is of growing importance in the production of blood products and therapeutic recombinant proteins.

The future is likely to see the continued development of high performance tangential flow filtration as a viable alternative to existing separation technologies for protein purification. There is also growing interest in the development of membrane systems for the preparation of enantiomerically enriched antibiotics, nutraceuticals and pharmaceuticals. These membrane systems use chiral ligands to separate racemic mixtures or they employ immobilized enzymes for direct production of single enantiomers in membrane reactors. Affinity membrane systems are also being actively pursued as alternatives to standard chromatographic resins for a range of adsorptive bio-separations. In this case, the membrane provides an attractive high surface area support with minimal diffusional mass transfer resistance. New advances in membrane materials, modules and processes

should lead to continued development of membrane systems for bioseparations.

more, methods of efficiently packaging membranes into modules (plate-and-frame, spiral-wound, and hollow-fibre) were developed during this period. Around 1980, the use of membranes for separations was established as a unit operation process in the chemical process industry. Further optimization of membrane preparation and modification methods from 1980 to 1990 made membrane separations competitive in gas separation and liquid separation applications. The most important production methods that resulted in the commercial use of synthetic membranes are listed in **Table 1**. Recent attention has been directed towards the development of inorganic membranes. Optimized inorganic membranes can have significantly better separation properties compared to state-of-the-art polymeric membranes. However, currently the main limitations for large-scale commercialization of inorganic membranes are their poor mechanical strength (brittleness) and extremely high manufacturing costs.

Membrane Types

Membranes can be distinguished based on their (i) geometry, (ii) bulk structure, (iii) production method, (iv) separation regime, and (v) application, as shown in **Figure 1**. Most commonly, membranes are produced in flat-sheet or tubular (hollow-fibre) geometry. Flat-sheet membranes are either packaged in plate-and-frame or spiral-wound modules, whereas tubular membranes are packaged in hollow-fibre modules. The choice of the optimum membrane and module type depends on a wide variety of process

specific conditions. Although hollow-fibre modules offer the highest membrane area per module volume ratio, plate-and-frame and spiral-wound modules are also commonly used for large-scale separations because of their better control of fluid dynamics.

Membranes either have a symmetric (isotropic) or an asymmetric (anisotropic) structure. The structure of a symmetric membrane is uniform throughout its entire thickness, whereas asymmetric membranes have a gradient in structure. The flux of a fluid through a symmetric membrane is typically relatively low, as the entire membrane thickness contributes a resistance to mass transport. Asymmetric membranes consist of two structural elements, that is, a thin, selective layer and a microporous substructure. Typically, the bulk structure (99+%) of an asymmetric membrane is highly porous and provides only mechanical strength. Separation of a fluid mixture in an asymmetric membrane is performed in a very thin surface layer, which is typically of the order of 0.1–0.5 μm thick. The most common symmetric and asymmetric membrane types are shown in **Figure 2**.

Ideal Membranes for Separations

Membranes can be fabricated from a wide variety of organic (e.g. polymers, liquids) or inorganic (e.g. carbons, zeolites, etc.) materials. Currently, most commercial membranes are made from polymers. The properties of a membrane are controlled by the membrane material and the membrane structure. To be useful in an industrial separation process, a

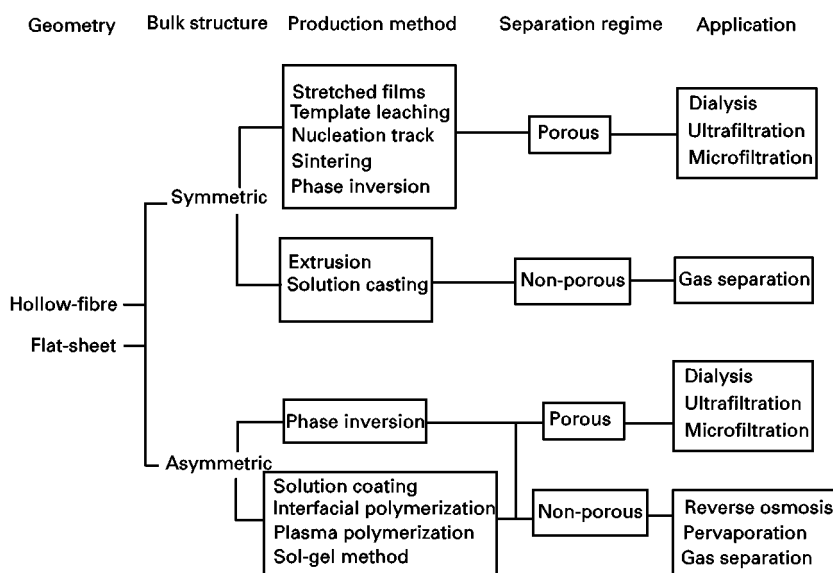

Figure 1 Classification scheme of synthetic membranes based on their geometry, bulk structure, production method, separation regime, and application.

Figure 2 Schematic representation of symmetric and asymmetric membrane structures.

membrane must exhibit at least the following characteristics: (i) high flux, (ii) high selectivity (rejection), (iii) mechanical stability, (iv) tolerance to all feed stream components (fouling resistance), (v) tolerance to temperature variations, (vi) manufacturing reproducibility, (vii) low manufacturing cost, and (viii) ability to be packaged into high surface area modules. Of the above requirements, flux and selectivity (rejection) determine the selective mass transport properties of a membrane. The higher the flux of a membrane at a given driving force, the lower is the membrane area required for a given feed flow rate, and, therefore, the lower are the capital costs of a membrane system. The selectivity determines the extent of separation, and, therefore, the purity of the desired product.

Typically, porous membranes are used in dialysis, ultrafiltration, and microfiltration applications. Ideal porous membranes have high porosity and a narrow pore size distribution. Membranes having a dense, selective layer are applied in reverse osmosis, pervaporation, and gas separation processes. Permeation through dense membranes occurs by a solution/diffusion mechanism. Ideal dense membranes should have a very thin selective layer, because flux is inversely proportional to the membrane thickness. In addition, the thin separating layer must be pinhole-free, because even a very small area fraction of defects in the membrane can cause a significant decrease in selectivity.

Polymeric Membranes

Currently, most commercial membranes are made from polymers. Polymeric membranes can be fabricated by a wide variety of methods and fulfill most of the requirements of an ideal membrane listed above. Membranes are made from amorphous as well as semi-crystalline polymers by solution- or melt-processes. A list of commonly used polymers for commercial membrane separation processes is given in Table 2.

Symmetric Membranes

Dense Symmetric Membranes

Dense symmetric membranes with thicknesses greater than 10 μm can be made by melt extrusion or solution casting and subsequent solvent evaporation. Because the fluxes of fluids through dense polymer films are very low, this membrane type is rarely used for large-scale separations. Dense symmetric, ion-exchange membranes are used in electrodialysis applications for production of potable water from brackish water.

Porous Symmetric Membranes

Typically, symmetric porous membranes have cylindrical, sponge-, web- or slit-like structures, and can be made by a variety of techniques. The most

Table 2 Polymers used for production of commercial membranes

important methods for the production of symmetric porous membranes are: (i) irradiation, (ii) stretching of a melt-processed semi-crystalline polymer film, (iii) template leaching, (iv) temperature-induced phase separation, and (v) vapour-induced phase separation.

Symmetric membranes with a cylindrical pore structure can be produced by an irradiation-etching process. These membranes are often referred to as nucleation track membranes. In the first step of this process, a dense polymer film, such as polycarbonate or polyester, is irradiated with charged particles, which cause chain scission and leave behind a sensitized track of damaged polymer molecules. These tracks are more susceptible to attack by chemical agents than the undamaged, base polymer film. In the second step, the film is passed through an etching medium, typically a sodium hydroxide solution. During this process, pores are formed by etching the partially degraded polymer along the nucleation tracks. Membranes made by this method have a very uniform pore size. The porosity and pore size of nucleation track membranes can be controlled by the irradiation time and etching time, respectively.

Membranes with a symmetric slit-like pore structure can be made from semi-crystalline polymers, such as polyethylene, polypropylene or polytetrafluoroethylene, using a melt extrusion/stretching process. In the first process step, a highly oriented film is formed by melt-extrusion of a semi-crystalline polymer and re-crystallization under high stress. The crystallites in the semi-crystalline polymer film are then

aligned in the direction of orientation. In the second step, slit-like pores, about 200–2500 Å wide, are formed between the stacked lamellae by stretching the membrane in the machine direction. The pore size of these membranes is determined by the rate and extent of stretching during the second process step. Commercial membranes made by the extrusion/stretching process are available from Hoechst-Celanese (Celgard®) and W.L. Gore (Gore-Tex®).

Template leaching is another method of producing symmetric microporous membranes by melt-processing of a semi-crystalline polymer. In this process, a leachable component, such as a high-boiling paraffin, is uniformly dispersed in a polymer melt. After extrusion and formation of a polymer film, the leachable component is extracted using a suitable solvent, and a sponge-like, microporous membrane is formed.

Symmetric porous membranes can also be made by a thermally-induced phase separation process (TIPS process). In the TIPS process, the membrane structure is formed by bringing an initially thermodynamically stable polymer solution to an unstable state by lowering the process temperature. The change in temperature causes phase separation of the initially stable solution into two phases with different compositions. The membrane structure depends primarily on the initial polymer concentration and the kinetics of the phase separation process and the local distribution of the polymer-rich phase at the point of solidification. A schematic phase diagram for a solution containing a polymer and a solvent is shown in Figure 3. The phase diagram is divided into three distinct regions: (A) stable polymer solution region, (B) meta-stable or binodal region, and (C) spinodal region. Phase separation can occur by two different mechanisms, that is, (i) nucleation and growth or (ii) spinodal decomposition. The quench paths of three different polymer-solvent solutions from temperature T_1 to temperature T_2 are illustrated in Figure 3. After lowering the initial solution temperature T_1 to T_2 , solutions A and B will be in the meta-stable region of the phase envelope and phase separation will occur by nucleation and growth. Solution A forms nuclei with composition ϕ_p^β (polymer-rich), whereas solution B will form nuclei with composition ϕ_p^α (solvent-rich). At equilibrium, both solutions phase-separate into two phases composed of ϕ_p^α and ϕ_p^β . However, the ratio of α -phase to β -phase is significantly different after phase separation of both solutions. Solution A will consist of a very small volume fraction of polymer-rich-phase (ϕ_p^β) dispersed in a large volume fraction of solvent-rich phase (ϕ_p^α). As a result of the low volume fraction of polymer, solution A will form a fine powder of precipitated polymer. On the other hand, solution B will consist of a small volume

Figure 3 Schematic diagram of a binary polymer-solvent system with an upper critical solution temperature (UCST).

fraction of solvent-rich phase dispersed in a large volume fraction of polymer-rich phase. The resulting morphology is a sponge- or foam-like porous structure. A thermal quench of solution C passes directly into the unstable region of the phase diagram; therefore, phase separation occurs by spinodal decomposition. Typically, phase separation by spinodal decomposition leads to an interconnected, porous structure. The final membrane structure depends not only on liquid-liquid phase separation phenomena but also on the kinetics of the thermal quench process and the distribution of the polymer-rich phase at the point of solidification. Typically, a rapid quench rate results in a large fraction of small pores, whereas a slow quench rate produces fewer, but larger pores.

Symmetric membranes with sponge- or web-like pore structures can also be made by a vapour-precipitation/evaporation technique. Membranes made by this method are highly porous and are typically used in microfiltration applications. In its simplest form of the method, a solution containing polymer, solvents and non-solvents is cast onto a substrate and is then exposed to a water-vapour-saturated air stream. The water vapour induces phase separation in the initially stable polymer solution. After phase separation, the solvent and non-solvent components are evaporated by blowing a hot air stream across the membrane. The porosity and pore size of this membrane type can be controlled by: (i) the polymer concentration in the casting solution and (ii) the composition of the vapour atmosphere. Low polymer concentration, high humidity, and the addition of solvent-vapour to the casting atmosphere lead to membranes with high porosity and large pore size. Because membranes made by the vapour-precipitation/evaporation method have an essentially constant polymer concentration profile throughout the entire membrane thick-

ness at the onset of phase separation, the resulting membranes are porous and have a fairly symmetric structure.

Asymmetric Membranes

The most commonly used asymmetric membranes are: (i) integral-asymmetric with a porous skin layer, (ii) integral-asymmetric with a dense skin layer, and (iii) thin-film composite membranes. Integrally-skinned asymmetric membranes are typically made by a non-solvent induced phase separation process (immersion precipitation) and consist of a thin, selective layer and a porous substructure. Both skin layer and substructure are formed simultaneously during the immersion precipitation process. Porous integral-asymmetric membranes are applied in dialysis, ultrafiltration, and microfiltration applications, whereas integral-asymmetric membranes with a dense skin layer are used in reverse osmosis and gas separation applications. Thin-film composite membranes consist of a thin, selective polymer layer atop a porous support. In this membrane type, the separation and mechanical functions are assigned to different layers in the membrane. This membrane type was originally developed for reverse osmosis applications; however, nowadays thin-film composite membranes are also used in nanofiltration, gas separation, and pervaporation applications.

Integrally-Skinned Asymmetric Membranes

The first integrally-skinned asymmetric membranes were developed by Loeb and Sourirajan in the early 1960s for seawater desalination by reverse osmosis. In the original Loeb-Sourirajan technique, thin-skinned ($\sim 0.2 \mu\text{m}$) cellulose acetate membranes were made by a four-step process: (i) casting of a multi-component polymer solution, (ii) partial evaporation of a volatile solvent, (iii) immersion of the nascent polymer film into a non-solvent (water), and (iv) thermal annealing of the water-wet membrane. Membranes made by this method had water fluxes orders of magnitude higher than those of thick, isotropic cellulose acetate films while maintaining high sodium chloride rejection ($> 90\%$). The Loeb-Sourirajan method has been modified and applied to a wide variety of polymers other than cellulose acetate. In fact, the Loeb-Sourirajan process is by far the most important method for production of commercial membranes for separations.

In the simplest case, integrally-skinned asymmetric membranes are made from a binary solution containing a polymer and a solvent. Upon immersion of the cast solution into a liquid (typically water), which is

a non-solvent for the polymer but miscible with the solvent, an asymmetric structure with either a porous or non-porous skin layer is formed. The structural gradient in an integrally-skinned asymmetric membrane results from a very steep polymer concentration

gradient in the nascent membrane at the onset of phase separation. The structure of a typical membrane made by immersion precipitation having a highly porous substructure and a thin skin layer is shown in Figure 4(A) and 4(B). In the immersion precipitation process, phase separation can be induced by: (i) solvent evaporation and/or (ii) solvent/non-solvent exchange during the quench step. Typically, the formation of membranes made by the immersion precipitation method occurs over a very short time scale, typically less than a few seconds. Most commercial membranes made by the immersion precipitation method are made from multi-component solutions containing polymer, solvent(s), and non-solvent(s) or additives. The porosity, pore size, and skin layer thickness can be modified by the addition of non-solvents to the casting solution (e.g. alcohols, carboxylic acids, surfactants, etc.), inorganic salts (e.g. LiNO_3 or ZnCl_2 , etc.) or polymers (e.g. polyvinylpyrrolidone, polyethylene glycol, etc.). Even very small amounts of these solution additives can have a significant effect on the membrane structure, and hence, its separation properties. The structure of membranes made by immersion precipitation can also be altered by using multi-component quench media. For example, the addition of a solvent to the quench medium results in an increase in the surface porosity and pore size of the membrane. The formation of membranes made by the immersion precipitation process depends on a large number of material- and process-specific parameters including:

- choice of the polymer (molecular weight, molecular weight distribution)
- choice of the solvent(s) and additives
- composition of the casting solution
- choice of the quench medium
- composition and temperature of the casting atmosphere
- temperature of the casting solution and quench medium
- evaporation conditions
- casting thickness
- casting or spinning speed
- membrane support material (type of woven or non-woven)
- drying conditions.

Thin-Film Composite Membranes

Composite membranes consist of at least two structural elements made from different materials, as shown in Figure 5. A single-layer composite membrane (5A) consists of a thin, selective layer atop a microporous support. The support provides only mechanical strength, whereas the separation is

Figure 4 (A) Porous bulk structure and (B) skin layer of an integrally-skinned asymmetric polysulfone membrane made by the immersion precipitation process.

Figure 5 Schematic diagram of (A) single-layer and (B) multi-layer thin-film composite membranes.

performed by the thin top-layer. A multi-layer composite membrane (5B) consists of a porous support and several layers of different materials, each performing a specific function. Thin-film composite membranes are applied in nanofiltration, reverse osmosis, gas separation, and pervaporation applications. The selective layer can be applied by lamination, solution coating, interfacial polymerization, or plasma polymerization methods. Compared to integrally-skinned asymmetric membranes, composite membranes offer several significant advantages: (i) independent selection of materials from which the separating layer and the porous support are formed, (ii) independent preparation of the separating layer and the porous support membrane, thereby making it possible to optimize each structural element, and (iii) very expensive membrane materials (> 1000 \$/lb) can be used because only a very small amount of polymer is required for the formation of the thin separation layer (~ 1 g polymer/m² of membrane for a 1- μ m-thick selective layer).

In most cases, porous, ultrafiltration-type membranes made by the immersion precipitation process are used as mechanical support for thin-film composite membranes. Optimum porous supports for thin-film composite membranes should have the following properties: (i) porous support must be chemically resistant against the solvent or solvent mixture from which the thin separating layer is formed and (ii) the porous support should have a high surface porosity and small pore size. High surface porosity is

important because the support should not provide any significant resistance to mass transport in a composite membrane. A small pore size is required for the deposition of ultrathin, defect-free coatings.

The two most important methods for the commercial production of thin-film composite are based on interfacial polymerization and solution coating methods. The first interfacially polymerized thin-film composite membranes were developed by Cadotte at the North Star Research Institute and represented a breakthrough in membrane performance for reverse osmosis applications. The original interfacial polymerization process involved soaking a microporous polysulfone support in an aqueous solution of a polymeric amine and then immersing the amine-impregnated membrane into a solution of a di-isocyanate in hexane. The membrane was then cross-linked by heat-treatment at 110°C. The resulting polyurea membrane had better salt rejection than that of an integrally-skinned asymmetric cellulose acetate membrane and high water flux. Modifications in the chemistry of the original interfacial polymerization reaction scheme resulted in further improvement in performance of thin-film composite membranes for reverse osmosis applications.

The solution-coating method involves deposition of a dilute polymer solution onto the surface of a porous membrane and subsequent drying of the thin liquid film. The simplicity of this process is very attractive for the production of membranes on a

commercial scale. However, it is generally very difficult to produce defect-free thin-film composite membranes with a thickness of less than 1 μm by the solution coating process. These defects are caused by incomplete coverage of surface pores in the support membrane after complete evaporation of the solvent. The difficulty in completely covering surface pores results from penetration of the coating solution into the porous support membrane structure. Because capillary forces in the porous membrane tend to pull the thin liquid polymer solution into the bulk support membrane, the coating layer can be disrupted easily. Several methods have been proposed to overcome problems with the formation of the thin, selective layer by the solution-coating process. One method is to use ultrahigh molecular weight polymers for the formation of the selective layer. An alternative approach for eliminating defects in the thin selective coating layer is to fabricate multi-layer composite membranes. These membranes, shown schematically in Figure 5B, consist of: (i) a porous support, (ii) a sealing layer, and (iii) an ultrathin, selective coating. The function of the sealing layer is to plug the pores in the support membrane and to provide a smooth surface onto which the thin coating layer can be applied. In addition, the sealing layer helps in channeling the permeating components to the surface pores, thereby rendering the entire surface area available for mass transport. The sealing layer should not provide a significant mass transport resistance in a multi-layer composite membrane. Hence, the sealing layer material should be significantly more permeable than the thin, selective top-layer.

Membrane Modification Methods

The development of high-performance polymeric membranes involves the selection of a suitable membrane material and the formation of this material into a desired membrane structure. However, it is often necessary to modify the membrane material or the structure to enhance the overall performance of the membrane. Generally, the objectives for modification of pre-formed membranes are: (i) increasing flux and/or selectivity and (ii) increasing chemical resistance (solvent resistance, swelling, or fouling resistance).

The first reported membrane modification method involved annealing of porous membranes by heat-treatment. Zsigmondy and Bachmann demonstrated in the early 1920s that the pore size of pre-formed nitrocellulose membranes could be decreased with a hot water or steam treatment. Loeb and Sourirajan used the same method to improve the salt rejection of integrally-skinned asymmetric cellulose acetate reverse osmosis membranes.

During the development of integrally-skinned asymmetric cellulose acetate gas separation membranes it was found that water-wet membranes collapse and form an essentially dense film upon drying. This collapse occurs because of the strong capillary forces within the finely porous structure during the drying process. This phenomenon can be described by the well-known Young-Laplace relationship ($\Delta p = 2\gamma/r$) in the case of perfect wetting of the liquid in the pores). Hence, the capillary pressure is directly proportional to the surface tension of a liquid, but inversely proportional to the pore radius. If the modulus of the membrane material (in the swollen state) is lower than the capillary force of the liquid in the pore space, the pores will collapse and form a dense polymer film. Because water has a very high surface tension, it is often difficult to dry water-wet membranes without collapsing the membrane structure. An exchange of water with liquids having lower surface tension, such as alcohols or aliphatic hydrocarbons, results in maintaining the original membrane structure upon drying. Typical solvent-exchange methods involve replacing water first with *iso*-propanol and then with *n*-hexane. Other methods of eliminating the collapse of finely porous membrane structures include freeze-drying and the addition of surfactants to the water prior to drying of the wet membranes.

In the 1970s, commercialization of gas separation membranes was severely limited by the very poor reproducibility of making ultrathin, defect-free membranes on a large scale. Methods for production of thin-film composite membranes as well as integrally-skinned asymmetric membranes with separating layer thicknesses of less than 0.2 μm were known. However, production of these membranes without defects was not possible. Defects as small as 20 \AA over an area fraction of less than $10^{-4}\%$ can severely reduce the selectivity of gas separation membranes. However, a thin coating of a highly permeable polymer, such as polydimethylsiloxane, can render defective membranes suitable for gas separations. Modification methods developed by Browall for thin-film composite membranes and, in particular, Henis and Tripodi for integrally-skinned asymmetric membranes resulted in rapid commercialization of gas separation membranes. Surface coatings are also applicable in improving the fouling resistance of membranes for ultrafiltration or nanofiltration applications. Chemical surface modification methods of gas separation membranes include treatment with fluorine, chlorine, bromine, or ozone. Typically, these treatments result in an increase in membrane selectivity coupled with a decrease in flux. Cross-linking of polymers is often applied to improve the chemical stability (swelling

resistance) and selectivity of membranes for electrodialysis, reverse osmosis, pervaporation, and gas separation applications.

Inorganic Membranes

Ceramic Membranes

Microporous ceramic membranes for ultrafiltration and microfiltration applications can be formed from a variety of metal oxides. Specifically, aluminium and titanium oxides are preferred precursors for the production of ceramic membranes. Because ceramic membranes are chemically inert and can be operated at high temperatures, these membranes offer some significant advantages over polymeric membranes. Pore diameters in ceramic membranes for ultrafiltration and microfiltration are in the 0.01 to 10 μm range and are typically made by a slip coating-sintering process. Other techniques, such as the sol-gel method, produce ceramic membranes with pores in the range of 10 to 100 Å. In the slip coating-sintering process, a porous ceramic tube is made by pouring a dispersion of a coarse ceramic material and a binder into a mould. This mixture is then sintered at high temperature. The resulting porous tube is then coated with a mixture containing very small metal oxide particles and a binder; this mixture is called a slip suspension. Again, the mixture is sintered at high temperature to form a more finely porous layer. The slip-coating-sintering method can be used to make membranes with pore diameters between 100 to 200 Å. More finely porous membranes can be fabricated by the sol-gel technique. First, the metal oxide, dissolved in alcohol, is hydrolyzed by addition of excess water. Then, the colloidal polymeric or inorganic hydroxide solution is cooled and coated onto a preformed microporous support made by the slip coating-sintering process. The coating must be dried very carefully to avoid cracking of the thin ceramic layer. The final step of the sol-gel method involves sintering of the coating at elevated temperature, typically between 500 and 800°C. In principle, membranes made by this process can be used in a variety of applications which require membranes that are stable in harsh environment and at elevated temperature. However, reproducibility of the membrane formation process on a large commercial scale is rather poor and the membrane costs are too high for these membranes to be used in any industrial separation process.

Metal Membranes

Metal membranes have been considered for a long time for gas separation applications, specifically hy-

drogen separation. Certain noble metals, for example palladium or palladium-silver and palladium-gold alloys, are permeable to hydrogen but essentially impermeable to all other gases. In the 1950s and 1960s, Union Carbide installed a pilot membrane system containing 25- μm -thick, isotropic palladium membranes. Because the hydrogen flux through these thick palladium membranes is quite low, the membranes had to be operated at about 400°C. Although the plant generated 99.9% hydrogen, commercialization of this process was economically not feasible because of the extremely high cost of the metal membrane ($\sim \$5000/\text{m}^2$). Furthermore, contaminants in the feed stream, such as hydrogen sulfide, poison the metal which results in a dramatic decline in hydrogen flux.

Anodic Membranes

Symmetric and asymmetric microporous membranes with a conical pore shape can be made from aluminium using an anodic oxidation process. Symmetric aluminium oxide membranes having a porosity of 65% and a pore size of about 200 nm can be made. The surface pores of asymmetric aluminium oxide membranes are about 25 nm. To prepare these membranes, a thin aluminium foil is anodically oxidized in an acid electrolyte, such as sulfuric or chromic acid, thereby forming an aluminium oxide. The unaffected fraction of the metal foil is subsequently removed using a strong acid. The pore size of membranes made by anodic oxidation is determined by the voltage and the acid type.

Carbon Membranes

Microporous carbon membranes can be made by compressing ultrafine carbon particles or by pyrolysing polymeric precursors. Degradation of the base polymer upon heating leads to carbonization. The pore size and porosity of the pyrolysed membranes depend primarily on the pyrolysis temperature and the pyrolysis atmosphere. Molecular sieve membranes made from pyrolysed polyacrylonitrile and polyimide as well as selective surface flow membranes made from polyvinylidene chloride-acrylate terpolymer can have significantly better separation performance than polymeric membranes in gas separation applications. The pore sizes of microporous carbon membranes are typically in the 5 to 20 Å range.

Glass Membranes

Isotropic glass membranes with a sponge structure can be made by thermal phase separation of an initially homogenous metal oxide mixture. Microporous

glass membranes were produced by Corning (Vycor®), Schott, and PPG. Glass membranes are typically made as discs, tubes or hollow-fibres. To produce microporous glass membranes, a homogeneous melt consisting of 70 wt% SiO₂, 23 wt% B₂O₃ and 7 wt% Na₂O is formed between 1300 to 1500°C. Phase separation of the initially homogeneous glass melt occurs by lowering the temperature to about 800°C. One phase consists primarily of insoluble silicon dioxide. The other phase, rich in alkali borate, can be leached from the heterogeneous glass by treatment with a mineral acid. After removal of the alkali borate phase, a microporous silica membrane is formed.

Future Developments

During the past forty years membranes have gained significant importance in a wide variety of industrial separations. Currently, polymeric membranes are most commonly used for commercial applications. However, recent developments on inorganic membranes are very promising and such membranes may broaden the separation spectrum of membranes for separations. The wide-spread use of inorganic membranes in industrial applications is currently limited by their poor mechanical stability and very high production costs. If these problems can be solved in future work, inorganic membranes will present a new generation of high-performance membranes for the next millennium.

Introduction

Microfiltration is a separation technique for removing micron-sized particles, like bacteria, yeast cells, colloids, and smoke particles, from suspensions or gases. The process uses membrane filters with pores in the approximate size range 0.1 to 10 µm, which are permeable to the fluid, but retain the particles, thus causing separation. Examples of particles with sizes in the microfiltration range are presented in **Figure 1**.

Microfiltration membranes were first commercialized in the 1920s, and were at that time mainly used for the bacteriological analysis of water. After 1960 the number of successful microfiltration applications

grew rapidly, and nowadays microfiltration processes are operated in such different fields as the biotechnological, automobile, electronics, and food industry. Examples of applications are the harvesting of bacterial and yeast cells, the recovery of latex pigments from paints, and the purification of water for the electronics industry. In the food industry, microfiltration is used in the clarification of fruit juices, wine, and beer, in fat removal from whey and in removal of bacteria from milk.

Microfiltration is the largest industrial market within the membrane field, responsible for about 40% of total sales, both in Europe and in the USA. In 1997, the US microfiltration membrane market amassed revenues worth about \$400 million, growing at an average annual growth rate of 6.6%. Microfiltration can be carried out in two different operation modes: dead-end (in line) filtration and cross-flow

glass membranes were produced by Corning (Vycor®), Schott, and PPG. Glass membranes are typically made as discs, tubes or hollow-fibres. Introduction

Microfiltration is a separation technique for removing micron-sized particles, like bacteria, yeast cells, colloids, and smoke particles, from suspensions or gases. The process uses membrane filters with pores in the approximate size range 0.1 to 10 µm, which are permeable to the fluid, but retain the particles, thus causing separation. Examples of particles with sizes in the microfiltration range are presented in **Figure 1**.

Microfiltration membranes were first commercialized in the 1920s, and were at that time mainly used for the bacteriological analysis of water. After 1960 the number of successful microfiltration applications

grew rapidly, and nowadays microfiltration processes are operated in such different fields as the biotechnological, automobile, electronics, and food industry. Examples of applications are the harvesting of bacterial and yeast cells, the recovery of latex pigments from paints, and the purification of water for the electronics industry. In the food industry, microfiltration is used in the clarification of fruit juices, wine, and beer, in fat removal from whey and in removal of bacteria from milk.

Microfiltration is the largest industrial market within the membrane field, responsible for about 40% of total sales, both in Europe and in the USA. In 1997, the US microfiltration membrane market amassed revenues worth about \$400 million, growing at an average annual growth rate of 6.6%. Microfiltration can be carried out in two different operation modes: dead-end (in line) filtration and cross-flow

Figure 1 Particles in microfiltration size range.

(tangential flow) filtration (**Figure 2**). In *dead-end filtration* the main flow direction is perpendicular to the membrane. The suspended particles are continuously dragged towards the membrane and deposit on the surface or inside the membrane pores. The deposition of particles leads to a continuously increasing resistance to flow and thus to a continuously decreasing permeate flux rate. To reduce this deposition process, microfiltration is often carried out in the *cross-flow mode* (tangential flow) in which the main flow direction is tangential to the membrane. The flow 'scours'

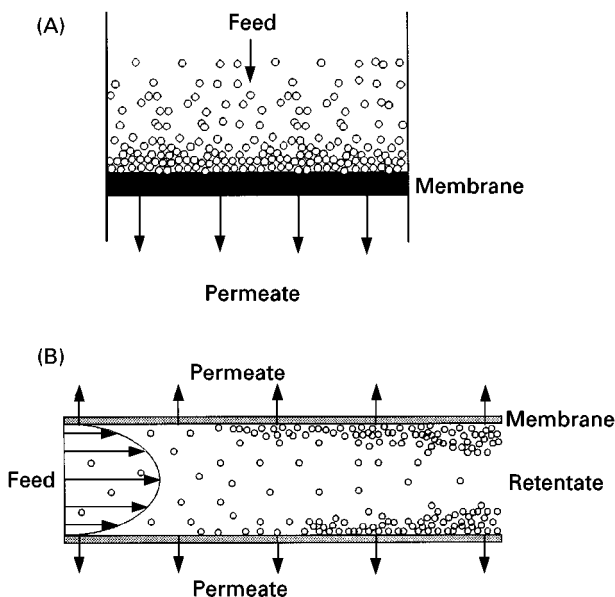

Figure 2 (A) Dead-end filtration and (B) cross-flow microfiltration using a tubular membrane.

away particles from the membrane surface, and thus limits particle deposition.

Microfiltration Membranes

Two main types of membrane filters exist: *screen filters* and *depth filters*. Screen filters contain capillary-type pores; particles are retained on the membrane surface primarily by a sieving mechanism. Depth filters contain a random, tortuous porous structure; particles are retained through adsorption and mechanical entrapment within the bulk of the filter. Screen filters are absolute: particles larger than the pore size are retained, whereas particles smaller than the pore size can pass relatively easily through the membrane. Particle retention of depth filters is not that clearly defined: retention values increase slowly over a broad particle size range and only reach 100% for very large particles. Depth filters are often used for dead-end filtration, as they can retain a high particle load.

Membrane Materials and Membrane Preparation

Microfiltration membranes are available in a wide variety of materials and methods of manufacture. Many membranes are made of polymers, such as cellulose acetate, polysulfone, and polyvinylidene fluoride (PVDF). Most of these membranes are solvent cast, through a phase inversion process. Other preparation techniques are stretching (polytetrafluoroethylene, PTFE, membranes) and track-etching (polycarbonate membranes). The track-etching process results in cylindrical pores with a very narrow size distribution.

Other microfiltration membranes available are made from glass, from ceramics, such as alumina, titania, and zirconia, and from metals, such as silver and stainless steel. Advantages of these inorganic materials are their higher stability towards extreme process conditions, such as high temperature, extreme pH values, and solvents different than water. Most metal and some ceramic membranes are produced by a sintering process, whereas other ceramic membranes are produced by sol-gel processing or by anodic oxidation. Some novel membranes are prepared by lithographic techniques.

In **Table 1**, a number of different commercial membranes and some of their key properties are presented, and in **Figure 3** SEM (scanning electron microscopy) and AFM (atomic force microscopy) images of some membranes are shown. Note that the membranes shown here are only a fraction of the total number of membrane materials and membrane manufacturers available.

Table 1 Various microfiltration membranes and their water fluxes

Manufacturer	Trade name	Material ^b	Preparation method	Pore size ^a (μm)	Water permeability at 20°C (L m ⁻² h ⁻¹ bar)
US Filter/SCT	Membralox [®]	α-Al ₂ O ₃	Sintering	0.2	2 000
Anotec	Anopore [®]	α-Al ₂ O ₃	Anodic oxidation	0.2	3 600
Carbon Lorraine		Carbon	Pyrolysis	0.2	1 500
Tech Sep	Carbosep [®]	ZrO ₂	Sintering	0.14	400
Millipore	Durapore [®]	PVDF	Phase inversion	0.22	5 900
	Fluoropore [®]	PTFE	Stretching	0.22	12 000
	MF-Millipore [®]	Mixed cellulose esters	Phase inversion	0.22	14 400
Osmonics	PCTE	Polycarbonate	Track-etching	0.2	14 600
	PES	Polyethersulfone	Phase inversion	0.2	20 500
	MCS	Mixed cellulose esters	Phase inversion	0.22	15 400
Whatman	Cyclopore [®]	Polycarbonate	Track-etching	0.2	16 000
Aquamarijn	Microsieve [™]	Silicon nitride	Photolithography	0.2	87 000

^aAll these membranes are available with pore sizes in large ranges. The pore sizes closest to 0.22 μm are mentioned here to compare water fluxes of the different membranes. ^bPVDF, polyvinylidene fluoride; PTFE, polytetrafluoroethylene.

Membrane Characterization

Originally the main goal in characterization of porous membranes was to determine the pore-size distribution. It has however been realized more recently that membrane surface properties, such as hydrophobicity, zeta potential and surface roughness, play an important factor in fouling and retention properties of membrane processes. Characterization is therefore nowadays performed by various techniques, measuring different structural and physico-chemical parameters. The relatively novel technique of AFM microscopy has been shown to provide information on many membrane properties of interest: pore size distribution, surface roughness, and adhesion behaviour. In **Table 2**, various measurement techniques are summarized.

Dead-end Microfiltration

In dead-end filtration, the fluid is forced perpendicularly through the membrane, while all or most of the particles are retained (Figure 2a). If screen filters are used, these particles build a cake layer on the surface, which causes an additional resistance to flow. If depth filters are used, these particles fill the voids within the membrane bulk, and in this way cause an increased resistance. For both types of filters, the increased resistance causes a continuous decline in flux if a constant transmembrane pressure is used (**Figure 4**). After some time, the flux has been reduced to unacceptably low levels, and the membrane has to be cleaned or replaced.

Dead-end filtration is preferred over cross-flow filtration in situations where the concentration of particles to be removed from the fluid is very low, as is

the case for sterile filtration in the pharmaceutical industry, for gas cleaning, and for guard-filters positioned as last step in a high-purity water unit. Dead-end filtration is also used in situations where backflush techniques and gas sparging are so effective that the use of a cross-flow is not necessary, as found in some wastewater-treatment plants.

Fluid Flow through Membrane Pores

The capacity of a microfiltration process is expressed as flux, J , which is the volume of permeate passing through the membrane of area A_m and per unit time:

$$J = \frac{1}{A_m} \frac{dV}{dt} \quad [1]$$

where V is the volume of permeate, and t is time: Most commercial liquid microfiltration processes operate at fluxes of typically about 10^{-4} m s^{-1} ($360 \text{ L m}^{-2} \text{ h}^{-1}$).

The driving force for this flux is the *transmembrane pressure* (most commonly written as ΔP), the pressure difference between feed side and permeate side, which results from applying either suction to the permeate side or pressure to the feed side, or both. Transmembrane pressures in liquid microfiltration are typically 5–100 kPa (0.05–1 bar). It was found phenomenologically that the flux increases linearly with the transmembrane pressure (Darcy's law):

$$J = \frac{\Delta P}{R_m \cdot \mu_0} \quad [2]$$

where μ_0 is the permeate viscosity, and R_m is the hydraulic resistance of the membrane against

permeate flow. The *permeability* of the membrane is defined as the inverse of its resistance ($1/R_m$). Microfiltration membranes have permeabilities of typically 10^{-11} m.

The permeability is related to the pore size. The exact relation between permeability and pore size depends on the geometry. For straight cylindrical pores, the Hagen–Poiseuille equation yields:

$$R_m = \frac{8l}{\varepsilon_m r_p^2} \quad [3]$$

where l is the membrane thickness, ε_m is the membrane porosity, and r_p is the pore radius. For membranes comprised of sintered spheres, the Kozeny–Carman equation may give a better approximation:

$$R_m = \frac{45(1 - \varepsilon_m)^2 l}{\varepsilon_m^3 a_m^2} \quad [4]$$

where a_m is the radius of the particles that constitute the membrane.

Figure 3 *Continued*

Screen Filters: Cake-layer Build-up

The flux calculated by eqns [2]–[4] is the so-called ‘pure water flux’. During filtration, fouling and cake-layer build-up continuously decrease the flux to values much lower than the pure water flux. Darcy’s law (eqn [2]) can be written for a fouled membrane as:

$$J = \frac{\Delta P}{R_{\text{tot}} \cdot \mu_0} \quad [5]$$

where R_{tot} is the total hydraulic resistance. It can be divided into the membrane resistance (R_m), the resistance caused by fouling (R_f), and the resistance caused by the cake layer (R_{cake}):

$$R_{\text{tot}} = R_m + R_f + R_{\text{cake}} \quad [6]$$

Fouling can be caused by processes such as the adsorption of macromolecules or bacteria. It is difficult

Figure 3 *Continued*

to predict the extent of fouling quantitatively; a qualitative description is given in a later section. The cake resistance can be calculated by the Kozeny–Carman equation, eqn [4], where the cake's void fraction ε , the cake-layer thickness δ_c , and the particle radius a are to be inserted for ε_m , l and a_m respectively.

The void fraction of the cake layer, ε , may depend on various parameters, such as transmembrane pressure, particle size distribution, shape, and compressibility, and the effect of particle–particle interactions. Often a value between 0.3 and 0.4 is found for ε .

A model for the time dependent dead-end filtration flux is obtained by combining eqns [4]–[6] with a mass balance describing cake layer build-up:

$$\left(\frac{d\delta_c}{dt} + J\right)\phi_b = (1 - \varepsilon) \frac{d\delta_c}{dt} \quad [7]$$

where ϕ_b is volume fraction of particles in the bulk.

If a constant ΔP is applied, the flux is given by:

$$J(t) = \frac{\Delta P}{\mu_0 R_m} \left(1 + \frac{2\hat{R}_c \phi_b \Delta P \cdot t}{(1 - \varepsilon - \phi_b) \mu_0 R_m^2}\right)^{-1/2} \quad [8]$$

where \hat{R}_c is the specific cake resistance ($= R_c / \delta_c$). Care must be taken when using eqn [8] as ε and \hat{R}_c often depend on time (cake compaction).

Depth Filters

Particle retention in depth filters is based on various mechanisms. In the case of gas cleaning, the two

Figure 3 Continued

most important mechanisms are particle capture by *interception* and particle capture by *diffusion*. Interception occurs when a particle follows a fluid stream-

line, which at some point passes close to the filter surface at a distance less than the particle radius, thus causing contact between the particle and the filter.

Table 2 Membrane characterization methods

<i>Method^a</i>	<i>Parameters obtained</i>	<i>Description/remarks</i>
<i>Microscopic techniques</i>		
SEM, TEM, FESEM (+ image analysis)	Pore-size distribution, pore morphology (surface roughness)	'Direct' observation by microscopes. Although these methods have many advanced possibilities, they are mostly used for determining the pore-size distribution in the membrane surface. Preparation of sample necessary
AFM (+ image analysis)	Pore-size distribution, morphology, surface roughness, particle-membrane interactions	See SEM (no preparation technique is necessary)
<i>Liquid penetration methods</i>		
Bubble point method	Largest pore available	Liquids will fill larger pores at low pressures. To fill smaller pores, however, higher pressures are needed Simple method, contact angle of membrane-liquid needs to be known
Extended bubble point method	Pore-size distribution	See bubble point method
Mercury porometry	Pore-size distribution	High pressures are necessary that may damage the membrane structure
Permporometry	Pore-size distribution	Vapour condensation in pores is measured. Rather complicated method
Solute retention	Pore-size distribution ('cut-off')	Membranes with smaller pores retain solutes of smaller sizes. Simple method. More often used for ultrafiltration than for microfiltration
<i>Contact angle measurements</i>		
Sessile drop, Wilhelmy plate	Contact angle, surface tension, hydrophobicity	Direct methods that measure the contact angle liquid-air-membrane. Give qualitative information on hydrophobicity
<i>Electrokinetic methods</i>		
Electroviscous method	Zeta potential, surface charge density	Experimentally simple: measurement of water flux at various ionic strengths. Interpretation of results more difficult
Streaming potential, electroosmosis	Zeta potential, surface charge density	Direct measurements of electrokinetic effects. Interpretation of results sometimes complicated

^aSEM, scanning electron microscopy; TEM, transmission electron microscopy; FESEM, field effect scanning electron microscopy; AFM, atomic force microscopy.

Capture by diffusion occurs when the Brownian motion of the particle results in contact between the particle and the filter matrix.

Interception is the dominant capture mechanism for large particles; Brownian diffusion is the dominant capture mechanism for smaller particles. Capture is therefore least effective for intermediate size particles, leading to the existence of a 'most penetrating particle size' (Figure 5). The exact value of this most penetrating particle size depends on the membrane pore diameter and the flow velocity. It has been found, however, that capture of particles from gas streams by membranes of pore diameters of about 0.2 μm is so effective that essentially all particles are retained.

For depth filtration of liquids, the situation is different, as physicochemical (charge) effects alter the relative magnitudes of the capture mechanisms described above. If physicochemical conditions are favourable, capture efficiencies in liquids can be similar to those in gases. If conditions are less favourable, capture efficiencies for the smaller particles decrease

rapidly. Under these conditions sieving (entrapment) is the only effective particle capture mechanism, making the membrane permeable for all particles smaller than the pore size.

Figure 4 Flux versus time for the dead-end microfiltration of a silica particle suspension.

Figure 5 Schematic representation of efficiency of capture by interception and capture by diffusion versus particle size. The most penetrating particle size is obtained by combining both mechanisms.

Cross-flow Microfiltration

Dead-end microfiltration, as stated, may suffer from dramatic flux loss because of deposition of particles on the membrane surface and fouling phenomena. Therefore microfiltration is often carried out in the *cross-flow* mode (Figure 2b). The tangential flow (cross-flow) ‘scours’ away particles from the membrane surface, and thus limits cake-layer build-up and fouling. Another advantage of cross-flow filtration is the possibility for continuous operation. Cross-flow filtration is used in most industrial large-scale microfiltration plants. For cross-flow microfiltration, screen filters are mainly used.

Cake-layer Build-up and Fouling

During a cross-flow microfiltration process, a flux behaviour is often observed as shown in Figure 6. The flux declines at first rapidly with time; then the speed of flux decline decreases, and finally a *steady state* is reached where the flux does not decrease anymore. The decrease in flux is commonly ascribed to two phenomena: *cake-layer build-up* and *fouling*.

When filtering a suspension, the membrane retains suspended particles. The particle concentration near the membrane will therefore gradually increase. Cake-layer build-up will occur when the particle concentration near the membrane surface reaches the maximum packing density (0.6–0.7). Cake-layer build-up is thus caused by the particles that are retained by the membrane based on their size, independent of any specific interaction between these

particles and the membrane. Cake-layer build-up in microfiltration is a phenomenon similar to *concentration polarization* in ultrafiltration.

Fouling, on the other hand, is based on a direct contact between solutes and the membrane surface. The term ‘fouling’ includes many processes, such as adsorption and deposition of macromolecules, bacteria, or small organic molecules on the membrane surface or within the pores. Fouling increases the hydraulic resistance against permeate flow, and thus reduces the capacity of the microfiltration process. Moreover, fouling in general increases the observed retention of the membrane as it reduces the effective pore size.

If one plots the steady-state flux for crossflow microfiltration versus transmembrane pressure (ΔP) often a curve as given in Figure 7 is obtained. Three regimes can be observed. For low values of ΔP , the flux increases linearly with ΔP and often equals the pure water flux. For higher values of ΔP , the flux curve bends, because of cake-layer build-up, and fluxes become less than the pure water flux. The point where the deviation from the straight line starts is often referred to as the *critical flux*. For even higher ΔP , the flux is independent of the pressure. This pressure independent flux value is referred to as the *limiting flux*.

Factors Influencing Membrane Fouling and Cake-layer Build-up

The extent of membrane fouling and cake-layer build-up depends on many parameters, which can be grouped in three main contributors:

- properties of the membrane,
- properties of the suspension, and
- properties of the process (hydrodynamics).

Membrane properties of importance are hydrophobicity, surface charge (zeta potential), surface

Figure 6 Flux versus time for the cross-flow microfiltration of a silica particle suspension.

Figure 7 Steady-state flux versus ΔP for the cross-flow microfiltration of a silica particle suspension. —, water; ---□---, silica particle suspension.

roughness, and pore-size distribution. In general, macromolecular adsorption is more severe for *hydrophobic* than for hydrophilic membranes. Fouling by negatively charged colloids is less for *negatively charged membranes* than for uncharged or positively charged membranes. As most colloids in practical suspensions acquire a negative charge, negatively charged membranes are preferred in general. Membrane fouling is further reduced by choosing membranes with *smooth surfaces*, small pore sizes, and *narrow pore size distributions*.

Feed suspension properties of importance are particle concentration, particle charge (zeta potential), ionic strength, and overall composition. The amount of cake-layer build-up increases with *particle concentration*. *Charge effects* can reduce fouling by membrane-particle repulsion, and can reduce cake-layer build-up by particle-particle repulsion. Such charge effects are less pronounced at high *ionic strength*, as the ions present in solution 'shield' the charge of membrane and particles. Overall composition of the feed suspension is of great importance for the fouling behaviour. Fouling may be caused not only by the main particles retained, but also by macromolecules and small organic molecules, which 'geometrically' should pass through the pores easily.

Process properties of importance are the transmembrane pressure and the cross-flow velocity. Low fouling normally occurs at low *transmembrane pressures* and high *cross-flow velocities*. More detailed information is given in a later section.

Calculating the Limiting Flux

To calculate the limiting steady-state flux, local mass balances near the membrane surface are used. It is

then assumed that the limiting flux is reached when the amount of particles transported *towards* the membrane by the permeate flux (convection) equals the amount of particles transported *away* from the membrane by the cross-flow. The cross-flow can cause back-transport by at least four different mechanisms:

- Brownian diffusion,
- shear-induced diffusion,
- inertial lift, and
- surface transport.

In the following, these mechanisms will be explained. It is assumed throughout this section that the particles are spherical and monodisperse, and that long-term fouling and physicochemical interactions are negligible.

Brownian diffusion If back-transport is caused by Brownian diffusion the standard concentration polarization theory can be used, employing the Brownian diffusion coefficient for spherical particles:

$$D = \frac{kT}{6\pi\mu_0 a} \quad [9]$$

where k is the Boltzmann constant, T is temperature, and a is the particle radius. By numerical calculations, using a suspension viscosity that depends on the particle concentration, it can be shown that the flux is given by:

$$J = 0.0769 \left(\frac{\tau_w k^2 T^2}{\mu_0^3 a^2 L} \right)^{1/3} \phi_b^{1/3} \quad [10]$$

where τ_w is the wall shear stress and L is the membrane length.

Eqn [10] predicts fluxes of the right order of magnitude for suspensions of small particles (up to about 10 nm). It under-predicts fluxes by one or two orders of magnitude if applied to suspensions of larger particles. This discrepancy is called the 'flux paradox'. This paradox is explained by assuming that there are other mechanisms for back transport, apart from Brownian diffusion.

Shear-induced diffusion When a shear field is applied to a layer of particles, the particles will tumble over one another, leading to a more loosely packed layer. Obviously the particles must move perpendicular to the applied shear stress to achieve this. The resulting particle migration can be described by employing an effective diffusion coefficient, and is called *shear-induced diffusion*.

It can be calculated, using an empirical value of the shear-induced diffusion coefficient, that the limiting flux is given by:

$$J = 0.060 \frac{\tau_w}{\mu_0} \left(\frac{a^4(1 - 3.8\phi_b)}{\phi_b L} \right)^{1/3} \quad [11]$$

valid for $\phi_b < 0.2$, i.e. for all practical applications. Eqn [11] has been shown to give good flux predictions for suspensions of hard spherical particles, and reasonable flux predictions for complex biofluids such as milk. Although eqn [11] is derived for local viscous flow, flux calculations have also been reported to be accurate for many *turbulent* flow processes.

Inertial lift If a diluted suspension of particles flows through a duct, particles present close to the wall will migrate towards the centre, perpendicular to the streamlines. This migration, caused by complex hydrodynamic interactions, is called inertial lift. In cross-flow microfiltration, inertial lift may be able to prevent particles from depositing onto the membrane. To model this phenomenon, it is assumed that a cake layer builds up during microfiltration until the convective velocity *towards* the membrane (the flux J) equals the lift velocity, v_L , *away* from the membrane:

$$J = v_L = 0.036 \frac{\rho_0 a^3 \tau_w^2}{\mu_0^3} \quad [12]$$

The inertial lift theory neglects the influence of a particle on the motion of another particle, resulting in a flux equation which does not depend on the particle concentration. The inertial lift model is therefore only valid for very low particle concentrations. As the flux predicted by eqn [12] increases with the cube of the particle size and the square of the wall shear stress, inertial effects are expected to be important only for large particles ($> 5 \mu\text{m}$) and high cross-flow velocities ($\tau_w > 10 \text{ N m}^{-2}$).

Surface transport A particle on top of a filter cake is subject to different forces, as shown in Figure 8. The horizontal drag force caused by the cross-flow F_τ exerts a clockwise torque on the particle, and the vertical drag force caused by the permeate flux F_J exerts a counterclockwise torque. If the torque caused by the cross-flow is larger than the torque caused by the permeate flux, the particle can *roll* over the cake layer to the outlet of the membrane. This mechanism of transport is called surface transport.

Equating the clockwise torque with the anticlockwise torque, an equation for the limiting flux is

Figure 8 Torque balance for the surface transport model. F_τ = horizontal drag force caused by the cross flow; F_J = vertical drag force caused by the permeate flux J ; F_i = particle–particle interaction force; θ = angle of repose.

obtained:

$$J = \frac{2.36 a \tau_w}{\mu_0 \tan \theta (a^2 \hat{R}_c)^{2/5}} \quad [13]$$

where θ is the angle of repose (see Figure 8).

Just as for the inertial lift model, the present model neglects the influence of a particle on the motion of another particle, resulting in a flux equation which does not depend on the particle concentration. Eqn [13] overpredicts fluxes for typical microfiltration conditions by an order of magnitude or more. Two of the models described above, the Brownian diffusion model and the shear-induced diffusion model, use a *continuum approach*. The other two, the inertial lift model and the surface transport model, are based on a *single-particle approach*. The single-particle approach is only valid for low particle concentrations and large particles.

In Figure 9, the fluxes predicted by the two continuum models are given as a function of particle size for typical cross-flow microfiltration conditions. The flux predicted by the inertial lift model is plotted in the same graph to indicate the order of magnitude of inertial effects. For small particle sizes, Brownian effects dominate and the flux decreases with particle size. For intermediate particle sizes, shear-induced diffusion dominates and the flux *increases* with particle size. For large particle sizes ($> 5 \mu\text{m}$) inertial effects dominate causing the flux to increase even faster with particle size.

The combined effect of Brownian and shear-induced diffusion can be described by:

$$J_{\text{Bo + SI}} = \sqrt{J_{\text{Bo}}^2 + J_{\text{SI}}^2} \quad [14]$$

Figure 9 Flux calculated according to different models as a function of particle diameter. Calculations were performed for $\tau_w = 32 \text{ N m}^{-2}$, $\phi_b = 10^{-3}$, and $L = 1.2 \text{ m}$, using eqns [10]–[12] for the Brownian, shear-induced, and inertial-lift models, and using eqn [14] for combining Brownian and shear-induced diffusion; ---, Brownian diffusion model; ·····, shear-induced diffusion model; —, Brownian and shear-induced diffusion model; ·····, inertial lift model.

where J_{Bo} is the flux according to Brownian theory, eqn [10], and J_{Si} is the flux according to shear-induced theory, eqn [11]. Predictions according to eqn [14] are also given in Figure 9.

Calculating the Transient Behaviour of Cross-flow Microfiltration

The time dependence of the flux can be predicted using an approach as outlined in the section on dead-end filtration, yet allowing for back-transport according to the particle transport mechanisms described above. Such descriptions are rather complicated, and will not be treated here.

A simple but effective approach to model the transient behaviour of the permeate flux is the use of a combination of transient dead-end filtration theory and a cross-flow filtration model for the steady-state (limiting) flux. While the cake is initially developing, the effect of the cross-flow is small and can be neglected, so that cross-flow filtration theory can be approximated by dead-end filtration theory. Upon approaching the steady state, the cross-flow begins to arrest the cake growth and dead-end filtration theory is no longer accurate. However, near the steady state the flux shows only minor time dependence, and the flux can be approximated by its steady-state value.

The procedure to predict the total transient behaviour of the permeate flux is thus to use dead-end filtration theory (see the section on dead-end microfiltration) until the time the steady-state flux is reached and then use the steady-state flux predicted by

Figure 10 Flux and amount of matter deposited on the membrane as a function of time for the filtration of a suspension of $0.48\text{-}\mu\text{m}$ silica particles. Circles represent experimental values for a particle concentration of 1.7 kg m^{-3} , a transmembrane pressure of 0.42 bar and a cross flow velocity of 1 m s^{-1} ; lines represent model calculations.

a steady-state cross-flow filtration model. This approach is illustrated in Figure 10, modelling the transient flux and cake-layer build-up in the cross-flow microfiltration of a suspension of silica particles.

Process Considerations

Cross-flow microfiltration is usually carried out in the feed-and-bleed mode, shown in Figure 11. The use of a retentate recycle makes it possible to work at high cross-flow velocities (high Q_c) while having low retentate flows (i.e. high volumetric concentration factors $V_c = 1 + Q_p/Q_R$). When high concentration factors are desired, several recirculation loops may be placed in series, or in even more complicated schemes, with loops both in parallel and in series (Christmas tree design).

In many cross-flow microfiltration systems and in some dead-end systems, *backflushing* is applied to remove the fouling layer from the membrane. Backflushing is achieved by forcing the permeate periodically back through the membranes. Effective backflushing is obtained by using high counterpressures

Figure 11 Feed-and-bleed operational configuration for cross-flow microfiltration.

Figure 12 Microfiltration flux when filtering a particle suspension, with and without backflush.

(about 0.5 bar) for several seconds every few minutes (Figure 12).

Fouling is reduced by high cross-flow velocities and low transmembrane pressures. High cross-flow velocities cause high-pressure drops along the membrane, which cause the ΔP to be undesirably high at the entrance of the membrane module. Therefore microfiltration processes have been developed which facilitate a cross-flow both on the feed side and on the permeate side. The pressure drops on both sides are similar in magnitude, guaranteeing a *uniform transmembrane pressure*. This method of operation has been shown to be effective in many dairy applications.

Other process techniques to reduce fouling are the use of pulsed flow, gas sparging, and electric or acoustic fields, and the use of flow geometries that create secondary flows or vortices resulting in high shear rates (e.g. the use of 'turbulence promoters' or curved channels).

Conclusions

Over the last 70 years, microfiltration has developed from a small specialized technology used only in

laboratories to a multibillion dollar industry for separation and purification of liquid and gas streams. Especially since the 1980s, exciting new applications have become possible, due to improved membranes (for example, ceramics) and improved technologies (for example, backpulsing, uniform transmembrane pressure). Still, great challenges exist, for example in the processing of beverages, such as fruit juices, milk, and beer, where membrane fouling seriously impairs the economy of the process.

To overcome these problems, researchers and engineers are becoming increasingly interested in hybrid and combined processes. Combining microfiltration with good pre- and post-treatments or with other separation processes may result in better and more economic separations.

Development

In 1917 PA Kober published a paper in which he described his observation that 'a liquid in a collodion

bag, which was suspended in the air, evaporated, although the bag was tightly closed'. Kober was not the first researcher to observe this phenomenon, but the first to realize its potential for the separation of liquid mixtures which otherwise are difficult to separate, and to separate them under moderate conditions. He introduced the terms 'Pervaporation', and 'Perstillation', and the first term is now in use to describe in

Figure 12 Microfiltration flux when filtering a particle suspension, with and without backflush.

(about 0.5 bar) for several seconds every few minutes (Figure 12).

Fouling is reduced by high cross-flow velocities and low transmembrane pressures. High cross-flow velocities cause high-pressure drops along the membrane, which cause the ΔP to be undesirably high at the entrance of the membrane module. Therefore microfiltration processes have been developed which facilitate a cross-flow both on the feed side and on the permeate side. The pressure drops on both sides are similar in magnitude, guaranteeing a *uniform transmembrane pressure*. This method of operation has been shown to be effective in many dairy applications.

Other process techniques to reduce fouling are the use of pulsed flow, gas sparging, and electric or acoustic fields, and the use of flow geometries that create secondary flows or vortices resulting in high shear rates (e.g. the use of 'turbulence promoters' or curved channels).

Development

In 1917 PA Kober published a paper in which he described his observation that 'a liquid in a collodion

bag, which was suspended in the air, evaporated, although the bag was tightly closed'. Kober was not the first researcher to observe this phenomenon, but the first to realize its potential for the separation of liquid mixtures which otherwise are difficult to separate, and to separate them under moderate conditions. He introduced the terms 'Pervaporation', and 'Perstillation', and the first term is now in use to describe in

general a process in which one component out of a fluid mixture selectively permeates through a dense membrane, driven by a gradient in partial vapour pressure, leaving the membrane as a vapour, and being recovered in a condensed form as a liquid.

In the years following Kober's publication a number of papers were published describing membranes and processes for pervaporation. Especially during the 1950s, the interest focused on pervaporation membranes and processes for the separation of different classes of hydrocarbons and of isomers and numerous patents were granted. Membrane materials disclosed were natural and synthetic rubbers, cellulose esters and ethers, and several treated and untreated polyolefines. None of this early membrane, however, was used in any industrial process, owing to insufficient flux and selectivity.

Pervaporation, vapour permeation and gas permeation are very closely related processes. The driving force is always a gradient in partial vapour pressure, and transport through the membrane can best be described by a so-called 'Solution-Diffusion-Mechanism'. In this mechanism it is assumed that a component of the feed having a high affinity to the membrane is easily and preferentially absorbed and dissolved in the dense membrane. Following a concentration gradient it migrates through the membrane by a diffusion process and is desorbed at the downstream side of the membrane. The separation characteristic of the membrane is thus governed primarily by the solubility of components in the membrane material and, to a lesser extent, by its diffusivity which even may counteract against the solubility separation.

In pervaporation and vapour permeation processes the partial vapour pressures of the components at the feed side are fixed by composition and temperature of the feed; they can be influenced only by increasing the temperature. Therefore, the driving force for the transport of matter through the membrane is applied by reducing the partial vapour pressure at the permeate side.

Different means have been proposed in order to effect this reduction of the permeate side partial vapour pressure:

- The permeate side of the membrane is swept with an inert gas in which the partial vapour pressure of the critical (preferential permeating) component is kept sufficiently low. If the gas stream cannot be wasted it has to be reconditioned and recycled.
- All permeating vapour is removed by means of a vacuum pump. The vapour may be condensed after recompression at the downstream side of the pump.

- The permeated vapour is condensed at sufficiently low temperatures. As the condenser surface will be installed at a certain distance to the permeate side of the membrane all non-condensable gases have to be removed from the permeate compartment in order to minimize permeate side pressure losses.

In most industrial installations the last has been proven to be the most effective and economical process.

In a pervaporation process the feed is applied as a liquid and all partial vapour pressures of the components in the feed mixture are at saturation level. Within the limits of membrane stability and process requirements, temperature and pressure on the feed side are free adjustable parameters.

In vapour permeation a vaporous feed mixture is applied, with at least the partial vapour pressure of the preferential permeating component at or close to saturation conditions. Temperature and pressure of the feed are linked by vapour-liquid equilibrium and can be chosen within these limits only.

In gas permeation all partial vapour pressures at the feed side are below saturation and the permeate can no longer be condensed. By increasing the total feed side pressure the driving force for the transmembrane transport can be adjusted.

Pervaporation treatment liquid feed mixtures is insofar unique compared with other membrane processes as the transport of matter across the membrane is coupled with a phase change from liquid to vapour. The heat of evaporation is extracted from the liquid feed and transported through the membrane, too. As a consequence the temperature of the feed is reduced, which reduces driving force and transmembrane flux. Different means such as heated modules have been proposed to replace the lost heat of evaporation. In general, the total membrane area is split into a number of segments (stages) arranged in series with intermediate heat exchangers between each two segments or stages.

Membranes and Modules

Membranes

With the much broader knowledge of membrane structure and membrane manufacture accumulated in the development of desalination membranes in the 1970s pervaporation processes gained new interest. The separation characteristic of a membrane process is determined by the difference in transport rates of the components through the membrane only, not by liquid-vapour equilibria, and azeotropic mixtures can easily be separated. Since only the heat of

evaporation of the permeate vapour is lost a single step membrane process saves energy compared with, e.g., distillation.

Two different types of pervaporation membranes were developed at about the same time in the beginning of the 1980s:

- Hydrophilic membranes, with a preferential permeation for water, used mainly for the removal of water from organic solvents and solvent mixtures, with an emphasis on azeotropic mixtures.
- Organophilic membranes for the removal of volatile organic components from water and gas streams.

In both applications composite membranes are used, allowing for very thin separation layers but with sufficient chemical, mechanical and thermal stability. Because the composite structure flat sheet configurations are preferred. The substructure of both types of pervaporation membranes is very similar: a porous support membrane with an asymmetric pore structure is laid onto a carrier layer of a woven or non-woven textile fabric and a basic ultrafiltration membrane is formed. On the free side of this porous substructure the pores have diameters in the order of 20–50 nm which widen up to the fabric side to the micrometre range. Polyester, polypropylene and similar fibres are used for the textile carrier layer; structural polymers such as polyacrylonitrile, polyetherimide, polysulfone, polyethersulfone and polyvinylidene fluoride form the porous support.

On this substructure a thin dense layer (in the range of 0.5–5 μm thick) is coated, which effects the separation. Different coating techniques are in use, most commonly a solution of the respective polymer in an appropriate solvent is spread onto the porous substructure. The solvent is then evaporated, followed by further treatment to effect cross-linking of the polymer.

In hydrophilic membranes the separating layer is made from cross-linked polyvinyl alcohol (PVA), from polyimides, or natural polymers such as chitosan or cellulose acetate (CA), with PVA dominant. For organophilic membranes, the separation layer is formed mostly from siloxanes such as polydimethylsiloxane (PDMS), or polyoctylmethyl siloxane (POMS).

In recent years new efforts have been made in academia and industry to develop new membranes for organic–organic separation. Of specific interest are the separation of olefins from paraffins, e.g. propene from propane, aromatics such as benzene or toluene from aliphatic hydrocarbons or the separation of the xylene isomers. To date, no industrialization has been achieved. The only industrial

processes in this area are the separation of the light alcohols methanol and ethanol from their mixtures with hydrocarbons, ethers and esters. The membranes in use are, however, more of the hydrophilic type, in which the more polar alcohols replace the water.

To date, only polymeric membranes have been applied in pervaporation and vapour permeation processes. Thermal, mechanical and chemical stability of the porous substructure are limiting the operation range of this type of membrane, more than the stability of the separating layer. Demand for higher operation temperatures and chemical resistance have stimulated the development of inorganic substructures, and porous ceramics in particular. These can be coated by cross-linked polymeric separating layers similar to those on polymeric substructures. In more recent developments organic separation layers are applied, either by coating the porous substructure with a layer of zeolites or by reducing the size of the pore to molecular dimensions. The separation mechanism of these membranes is even more complex than that of polymeric separating layers, as molecular sieving effects, caused by shape and size of molecules, and molecule–surface interaction decide whether a component can pass through the membrane or will be retained.

Modules

Design of modules for pervaporation and vapour permeation processes was based on the experience gained in water treatment by membranes, such as ultrafiltration and reverse osmosis processes. However, significant modifications had to be made because of the specific requirements of pervaporation and vapour permeation processes.

The partial vapour pressure at the permeate side has to be reduced in both processes to fairly low values, especially when low final concentrations have to be reached in the retentate. Therefore any pressure losses, even in the range of a few millibars have to be avoided at the permeate side. Since any feed mixture will contain organic components at high concentration, mostly at elevated temperatures, the chemical stability of all module components, such as spacer and potting material and glues is critical. To date, two types of modules are most widely applied:

- Plate modules, mainly used for dehydration applications, with permeate channels as open as applicable. Stainless steel is used as a construction material for support plates for the membranes and for spacers. The permeate channels are preferably open over the circumference of the modules which

Figure 1 Vapour-liquid equilibrium curves for common pharmaceutical solvents which azeotrope with water. All can be dehydrated using pervaporation.

are assembled inside a special vacuum vessel that also house the permeate condenser. Alternative designs are very similar to plate heat exchangers, in which the supported membrane replace the heat exchanger plates. These modules are closed to the outside, with internal ducts feed and retentate, and for permeate removal.

- Spiral wound modules with stainless steel central tubes, but otherwise similar to those known from the conventional membrane processes, are mainly used for organophilic membranes. One or several of the spiral wound modules are housed inside a pressure tube and assembled in conventional skids. In a special design, the sandwich structures of membranes and permeate and feed spacer are welded together and not spirally wrapped around the central tube but arranged as flat sheets on the central tube for the removal of the permeate.

Very rarely, hollow fibres are used, generally with the feed flow inside the bore of the fibre. For the more conventional arrangement – feed flow at the shell side of the fibre – permeate pressure losses inside the bore may become detrimental for the process.

Applications

Organophilic Membranes

Organophilic membranes are mostly applied for the removal of volatile organic components (VOCs) from a gas stream such as waste air or nitrogen. The main applications are the treatment of streams originating from the evaporation of solvents in coating processes in film and tape production, purging of products such as polymers, by which unreacted monomers are removed, or from breathing of storage tanks for sol-

vents, especially from loading and unloading of petrol tanks in tank farms. In many installations the feed stream received at atmospheric pressure is compressed in order to increase the feed side partial vapour pressure. Partial condensation of the component to be removed is a wanted side effect, since then condensation on the permeate side under vacuum and at low temperature can be avoided. The permeate is simply slightly compressed by the vacuum pump and let into the inlet of the feed compressor. In specific cases the installation of a vacuum pump will not be necessary and the permeate is obtained at atmospheric pressure.

The economy of the process is usually determined by the value of the components recovered. Emission regulations in all industrial countries demand for very low final concentrations if the gas stream is released to the atmosphere, therefore the retentate from the gas purification by the membrane is either recycled or followed by an additional polishing step.

Although considerable efforts in research and development have been devoted to the removal of

Table 1 Solvents routinely dehydrated using pervaporation/vapour permeation

Isopropanol, ethanol	Standard applications for pervaporation, typically dehydrated from their azeotropes to fractions of a percent of water. Many continuous, batch and vapour permeation units are operating around the world.
Ethyl acetate, butyl acetate	Form azeotropes in the miscibility gap and were traditionally dehydrated by two distillation columns and a phase separator, however with a massive recycle. Esters decompose in contact with zeolites. Pervaporation/vapour permeation is easily the best technique for dehydration.
Acetone	Does not azeotrope with water but when distilled a large reflux is required to get a half dry product. Pervaporation is ideal for final dehydration or for debottlenecking existing distillation systems.
Tetrahydrofuran	Easily dehydrated by pervaporation down to a few hundred ppm water. Traditional caustic washing is operationally messy, requiring a redistillation of the product. Pressure swing distillation requires high pressures and large recycles.
Methyl ethyl ketone	Pervaporation is again the preferred technique. Distillation is only possible with an entrainer because the azeotropic composition is nearly identical to the miscibility limit.
N-butanol, n-propanol	Form azeotropes with high water content so the distillation/phase separation process involves massive recycle streams. Pervaporation plants are less costly to build and easier to operate.

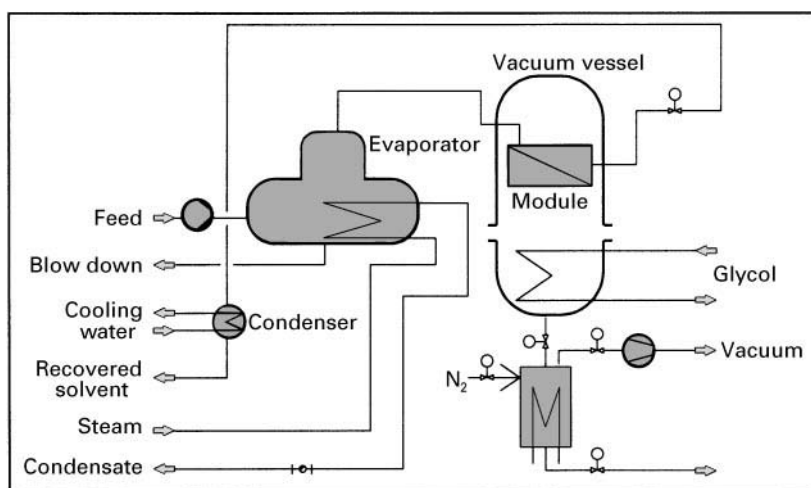

Figure 2 Typical flow diagram for recovery of solvent from mother liquors.

VOCs from aqueous stream, this technique has not yet been introduced into the industry. Potential mixtures which could be treated are more complex, the economical value of the recovered substances are low, and competing processes such as biological treatment of wastewater are cheaper. Applications may be found in the future in biotechnological processes where high-value products can be separated from a fermentation broth and be concentrated and purified in the same step.

Figure 3 (See Colour Plate 51). Vapour permeation unit for recovering ink solvent.

Hydrophilic Membranes

The largest industrial installations of pervaporation and vapour permeation processes are equipped with hydrophilic membranes which are used for the removal of water from organic solvents and solvent mixtures.

Solvent dehydration Organic solvents are used for a variety of purposes in the chemical industry, e.g. for synthesis of pharmaceuticals, to precipitate materials from aqueous solutions, for cleaning purposes and for drying final products. Spent solvents nearly always contain some water. Dehydration is therefore an essential step in their recovery but difficult since most solvents form azeotropes with water. Final water removal by distillation is then impossible or complicated. Entrainer use is not an option for pharmaceutical or fine chemical production, where stringent process certification rules out adding potential sources of contamination.

Pervaporation enables solvents to be dehydrated without using any third substance or entrainer, simply, cheaply and without problems and irrespective of vapour/liquid equilibria (Figure 1). On-site solvent recovery using pervaporation and vapour permeation is thus becoming standard practice in the pharmaceutical and chemical industries (Table 1).

Often, pervaporation and vapour permeation plants are designed for operation with a number of solvents and with mixtures of solvents. Pervaporation and vapour permeation offers the following benefits when dehydrating solvents:

- No introduction of additional chemicals, complete solvent dehydration by pervaporation membranes irrespective of azeotrope formation and no possibility of contamination.

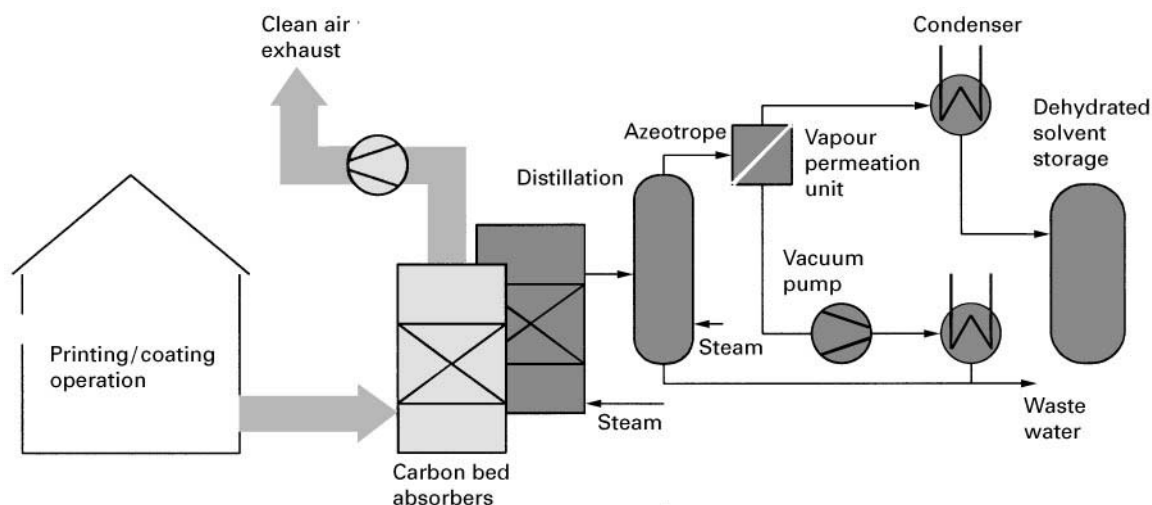

Figure 4 Carbon bed adsorption using steam regeneration and vapour permeation for final solvent dehydration.

- A choice of batch or continuous pervaporation systems, or continuous vapour permeation, depending on the duty.
- Able to dehydrate esters without any decomposition.
- Low energy consumption.

Solvent recovery from mother liquors Spent solvents (mother liquors) typically contain some water and are often saturated with dissolved material. They cannot be re-used without purification. Evaporation combined with vapour permeation is a powerful technique for purifying and dehydrating mother liquors (Figure 2).

The feed of spent solvent is evaporated and the resulting vapour is fed directly to a vapour permeation unit. Water vapour selectivity permeates the membrane and is condensed under vacuum. The water-free solvent vapour leaving the vapour permeation unit is condensed and is stored for re-use (product). A blowdown is taken from the evaporator to prevent buildup of dissolved solids. This purge can

be treated to recover valuable components. Combining evaporation with vapour permeation gives the following benefits: only vapour is fed to the membranes – no possibility of fouling and no possibility of solids carryover into the recovered solvent; both the evaporation and the vapour permeation process steps are carried out in a single unit.

Solvent recovery from carbon bed adsorbers Biodegradable solvents such as alcohols and esters are used in many specific applications in coating and printing. Typically, a solution of the coating material is applied to the surface and the solvent is evaporated into an air stream, leaving a uniform film of coat material. The use of volatile solvents speeds the drying process.

The solvent-laden air stream cannot normally be discharged. It must be cleaned up and because the solvent loading is usually quite low, carbon bed adsorbers are most commonly used. These adsorbers are periodically regenerated, using either steam or nitrogen. Solvent is then recovered from the condensate

Figure 5 Use of vapour permeation to recover solvent from nitrogen desorption circuit.

Figure 6 Vapour-liquid equilibrium diagram for acetone-water.

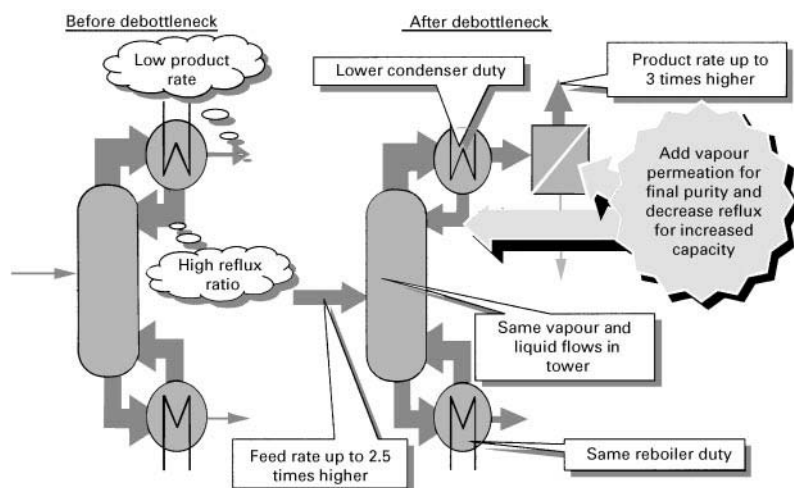

Figure 7 Debottlenecking a single pinched column using pervaporation (acetone–water example).

or nitrogen stream for re-use in the coating/printing process (Figure 3).

To evaporate quickly, the recycled solvent has to be substantially dry and because most of the organics used form azeotropes with water, distillation is not sufficient for final dehydration. Pervaporation or vapour permeation provides a dry solvent at minimal cost.

Vapour permeation for solvent dehydration in printing and coating If carbon bed adsorbers are regenerated with steam, the condensate is typically steam distilled up to the azeotrope (Figure 4). Continuous coating operations use continuous distillation to concentrate condensate from the bed regeneration. A vapour permeation system is normally connected directly to dehydrate net overhead vapour

from the distillation. This situation is shown schematically below. In this case, no additional energy is required for the final dehydration by vapour permeation.

Vapour permeation for solvent removal from circulating nitrogen If nitrogen is used to regenerate the carbon bed, solvent vapour can be continuously removed by vapour permeation through an organophilic membrane. This is much more economical than cooling the vapour to condense the solvent; because the solvent loading is low (Figure 5).

The use of vapour permeation for solvent recovery in printing and coating operations provides the following benefits: ethanol, isopropanol, ethyl acetate and other biodegradable solvents are recovered and dehydrated without entrainers and economically,

Figure 8 (See Colour Plate 52). Standard unit for batch dehydration of rinse alcohol.

Figure 9 Batch pervaporation process for dehydration of rinse alcohol.

Figure 10 Water removal by distillation and vapour permeation.

even at a modest scale; solvent can be economically recovered from nitrogen streams with minimal cooling requirement.

Debottlenecking Distillations

Debottlenecking pinched distillations Distillation processes are driven by volatility differences. If these volatility differences are small, or become small under certain conditions, then columns need to operate with high reflux to achieve the desired separation. Because pervaporation/vapour permeation processes separate irrespective of volatility differences, they can

be used very effectively to debottleneck pinched distillations.

Consider for, example, the system acetone–water (Figures 6 and 7). Acetone is concentrated in the vapour phase at low concentrations so stripping of acetone from water is easy. At high concentrations this is not the case. Complete dehydration of acetone is difficult.

Debottlenecking entrainer distillation systems Existing entrainer distillation systems can also be effectively debottlenecked using pervaporation/vapour permeation. Normally, the rectification column will be operating to give a product as close to the azeotrope as possible, running with a high reflux. To debottleneck the system, reflux in the rectification column is reduced, giving more overhead product, but with a higher water content. The pervaporation unit is sized to remove enough water that the subsequent entrainer column is also unloaded. Both columns can then realize a significant capacity increase.

The pervaporation unit required for debottlenecking is relatively small since the driving force for water permeation is high. Adding a pervaporation/vapour permeation system to a pinched distillation can give providing higher product capacity and reduced re-

Figure 11 Progression of a batch esterification (with equilibrium constant $K = 4$) with continuous water removal by pervaporation.

Figure 12 Some methanol azeotropes which can be separated using pervaporation vapour permeation.

flux, significantly higher products purity and reduced energy costs.

Dehydration and Purification of Rinse Alcohol

Many metal components used in the electronics industry undergo a rinse process using ethanol or isopropanol. Typically, the surface is first treated in another way to remove contaminants and then washed with water. The final rinse with alcohol displaces the water and any remaining contaminants and also wets the surface completely. The volatile alcohol then dries uniformly leaving a clean unmarked surface. Because the rinse alcohol displaces water it gradually becomes diluted and loses its drying qualities. Either fresh alcohol must be purchased or the alcohol must be dehydrated and purified to restore its performance.

The purity of the rinse alcohol is critical for component performance; wafer fabrication, for example, sets p.p.b. limits on certain metal ions (Figure 8).

Various standardized pervaporation/vapour permeation systems are now used economically and at

a site scale for dehydration and purification of rinse alcohol. A batch of used alcohol is continuously circulated from a buffer tank via a recuperator, heater and pervaporation module and water vapour is continuously removed via the vacuum pump (Figure 9). The batch is processed until the required degree of dryness is reached. Standardized units economically treat batches as small as $1 \text{ m}^3 \text{ day}^{-1}$.

Use of pervaporation and vapour permeation units to recover rinse alcohol gives the following benefits: minimal alcohol losses, very high product purities can be reached, and economical recovery at site scale.

Continuous Water Removal from Condensation Reactions

Condensation reactions such as esterifications, acetalizations and ketalizations produce water as coproduct; removal of this water from the reaction will shift the equilibrium in favour of the desired product.

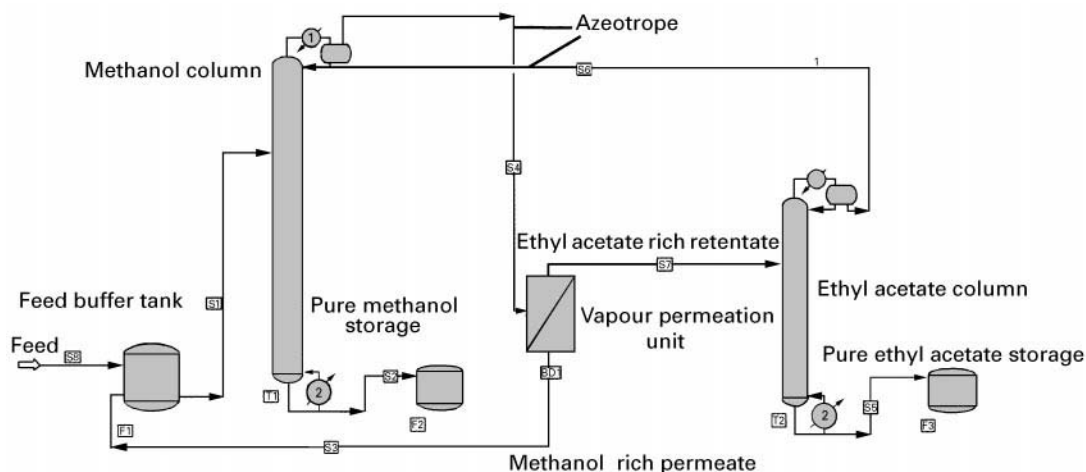

Figure 13 Methanol recovery by azeotrope breaking (methanol-ethyl acetate example).

Figure 14 Methanol removal by pervaporation of column side-draw.

Distillation is often used to remove water from condensation reactions. However complete water removal is difficult because alcohols, esters and acids typically azeotrope with water. Boiling the reaction mix also removes alcohol, which is normally the most volatile component including a vapour permeation unit after the distillation step avoids the problems of azeotrope formation. Water can be completely removed (Figure 10).

Water removal by pervaporation only – membrane reactors Removing water directly from the reaction mix is more effective – the reaction can even be run under stoichiometric conditions. Reactor configuration is simpler and energy consumption is much lower (Figure 11).

Using pervaporation/vapour permeation units to continuously remove water from condensation reactions gives the following benefits: complete conversion, maximum yield, minimum reagent consumption and costs; maximizes reaction kinetics, reactor efficiency and productivity; minimizes product purification costs; works irrespective of azeotrope formation.

Methanol Recovery

Methanol is commonly used as both solvent and reactant in the chemical industry. However, it forms azeotropes with many substances, particularly esters (Figure 12). Methanol often cannot be removed from spent solvents or from reaction mixtures with simple distillation. Some quite complicated processes have been developed to get around this problem.

Industrial pervaporation/vapour permeation units are now used for separation of methanol, either stand alone or in combination with distillation.

Methanol recovery by azeotrope breaking By way of example, a separation scheme for a methanol-rich methanol–ethyl acetate mixture is shown below. The mixture is distilled to the azeotrope, taking pure methanol out as bottom product. The overhead stream is passed directly to a vapour permeation unit which permeates a methanol-rich stream. This stream is condensed and passed back to the methanol column via the feed buffer. Retentate from the vapour permeation unit, strongly depleted in methanol, can be fed directly to the ethyl acetate column. Pure ethyl acetate leaves this column as bottom product while overhead azeotrope is sent to the vapour permeation unit (Figure 13).

Many solvent or ester/methanol mixtures can be separated using a similar scheme. If the feed is close to the azeotrope then the methanol column can be dispensed with. If the capacity is small the purification column for the second component may not be required, depending on the desired purity.

Institut Français du Pétrole (IFP) has developed a process where pervaporation of methanol is used to debottleneck MTBE production. In the debutanizer columns used in MTBE processing, the MTBE–methanol azeotrope results in a concentration of methanol at a point midway between the feed tray and the reboiler (Figure 14). Pervaporating methanol out of the process from a side-draw taken at this point results in methanol free MTBE as debutanizer bottom product.

Separation systems based on pervaporation/vapour permeation of methanol offer the following benefits: problem-free separation of methanol/organic mixtures irrespective of azeotrope formation; avoids water wash for methanol removal; minimum energy costs.

Dialysis and reverse osmosis

Dialysis is a separation process with increasing areas of application in clinical, biochemical and environmental analysis. A donor and an acceptor solution are separated by a semipermeable membrane (Figure 1).

Figure 1 Dialysis between quiescent and stirred solutions. C, concentration; D, donor solution; A, acceptor solution; M, membrane; d_A , d_D and d_M ; thicknesses of the corresponding phase layers, δ_A and δ_D ; thicknesses of the diffusional boundary layers.

When the solutions have different solute activities a diffusional membrane transport from the more to the less concentrated solution takes place to establish the thermodynamic equilibrium. In most applications mass transfer to and away from the separation membrane is accelerated convectively by stirring or by the use of flow-through separation cells.

When the solutions have different solvent activities an osmotic pressure is built up, which causes a solvent flow to the solution of the lower solvent activity. This process is termed osmosis. Reverse osmosis is defined as a process during which an outer pressure is applied to force the solvent through a membrane, which is permeable to the solvent and rejects the solute. Reverse osmosis is applied to purify water for laboratory use and is very promising as a preconcentration technique in trace and environmental analysis.

Fundamentals

Thermodynamic Aspects

During dialysis the activities of the solute i in the donor and the acceptor solutions differ. The difference between the chemical potentials $\mu_{i,D}$ and $\mu_{i,A}$ is the free enthalpy per mole, which propels the dialysis. The dialysis finishes when the thermodynamic equilibrium shown in eqn [1] is reached:

$$\mu_{i,D} = \mu_{i,A} \quad [1]$$

The equilibrium constant K_i^* depends on the activity coefficients $f_{i,D}$ and $f_{i,A}$ and the absolute temperature T according to eqn [2]:

$$K_i^* = \frac{a_{i,A}}{a_{i,D}} = \frac{f_{i,A} \times c_{i,A}}{f_{i,D} \times c_{i,D}} = \exp \left[\frac{\mu_{i,D}^0 - \mu_{i,A}^0}{RT} \right] \quad [2]$$

where $\mu_{i,D}^0$ and $\mu_{i,A}^0$ are the chemical potentials of the solute under standard conditions. c is concentration and a is activity. R is the molar gas constant. An effective separation ratio K_i , which is defined

according to eqn [3], is of analytical interest:

$$K_i = \frac{c_{i,A}}{c_{i,D}} \quad [3]$$

The activity coefficients f_i depend on the solvent, the ionic strength $I = \sum z_j c_j$ of the solution and the concentrations of all nondissociated solutes. The general index, j , labels the ions in the system with the electric charge z_j . Because in most cases:

$$\mu_{i,D}^0 - \mu_{i,A}^0 = 0 \quad [4]$$

it follows that:

$$K_i^* = 1 \quad [5]$$

and:

$$K_i = \frac{f_{i,D}}{f_{i,A}} \quad [6]$$

K_i differs from unity when the dialysis equilibrium is coupled to other equilibria and/or the activity coefficients $f_{i,D}$ and $f_{i,A}$ are different. Without coupled pushing and trapping reactions the enrichment E and the purification factor P can be calculated according to eqns [7] and [8]:

$$E = \frac{c_{i,A}}{c_{i,D,0}} = \frac{(c_{i,D,0} - c_{i,D})V_D/V_A}{c_{i,D,0}} \quad [7]$$

$$P = \frac{c_{i,D,0} - c_{i,D}}{c_{i,D,0}} = \frac{(c_{i,A} - c_{i,A,0})V_A/V_D}{c_{i,D,0}} \quad [8]$$

where $c_{i,D,0}$ and $c_{i,A,0}$ are the initial solute concentrations in the donor and in the acceptor solution, respectively, and V_A and V_D are the volumes of the corresponding solutions. The maximum enrichment factor is around 0.5 for $V_A \leq V_D$. The purification factor increases up to unity with the increasing ratio of V_A to V_D .

The chemical activities of the solvent are equal at dialysis equilibrium. According to eqn [9]:

$$\mu_{L,D} = \mu_{L,A} \quad [9]$$

and because:

$$\mu_{L,D}^0 = \mu_{L,A}^0 \quad [10]$$

it follows for the solvent L that:

$$K_L^* = \exp \left[\frac{1}{RT} \{ V_{L,D} \pi_D - V_{L,A} \pi_A \} \right] \quad [11]$$

where $V_{L,D}$ and $V_{L,A}$ are the partial molar volumes of the solvent which are equal to V_L for dilute solutions, and π refers to the osmotic pressure. It therefore follows that:

$$K_L^* = \exp \left[\frac{V_L}{RT} (\pi_D - \pi_A) \right] \quad [12]$$

with the osmotic pressure difference $\pi = \pi_D - \pi_A$. A volume change is effected to equilibrate the donor and the acceptor solutions. π can be calculated for every solution according to eqn [13]:

$$\pi = - (RT/V_L) \ln a_{x,L} \quad [13]$$

where $a_{x,L}$ is the activity ($x_L \cdot f_L$) of the solvent with respect to the mole fraction x_L of the solvent. Therefore the osmotic pressure difference π has to be taken into consideration to calculate precisely almost all dialysis equilibria. The osmotic pressure difference causes a solvent flow through the separation membranes up to the state at which the hydrostatic back-pressure compensates for the osmotic pressure. e.g. in the batch-type arrangement shown in Figure 2. If the pressure p_h is greater than the osmotic pressure the osmosis will be reversed. This reverse osmosis reaches an equilibrium, which can be described by eqn [14]:

$$K_L^* = \exp \left[\frac{V_L}{RT} (\pi - p_h) \right] \quad [14]$$

Obviously the equilibrium constant decreases with increasing pressure p_h . When the solute is rejected by the membrane it can be enriched in the donor solution.

To take into consideration the electric charges z_i of the solutes and of the separation membrane the Donnan effect has to be considered. The chemical potential μ_i is extended by a term for the electric potential gradient, ϕ . When a membrane separates

Figure 2 The principles of osmosis and reverse osmosis. M, membrane; p_h , outer pressure; π , osmotic pressure difference. ■, Aqueous salt solutions; □, water.

two solutions of a dissociating salt BA and one solution contains a rejected ion X^- , an electric potential difference $\phi = \phi_D - \phi_A$ is built up between the solutions. This Donnan potential influences the effective separation ratio K . The equilibrium constant is shown in eqn [15] with the Faraday constant F :

$$K_i^* = \exp[(\phi_D - \phi_A)z_i F/RT] \quad [15]$$

where F is the membrane area that is in contact with the solutions.

An outer electrical voltage U generates an electromigration of the anions to the positively charged anode and of the cations to the negatively charged cathode (Figure 3). The process is termed electrodialysis. If the potential difference between the electrodes U is smaller than the voltage U_D of the water decomposition a new electrochemical equilibrium is built up with the constant shown in eqn [16]:

$$K_i^* = \exp[(\phi_D - \phi_A + U)z_i F/RT] \quad [16]$$

In many practical applications the dialysis equilibrium is coupled with chemical equilibria, e.g. acid-base, redox, complexation and precipitation equilibria. It should be noted that distribution equilibria between two different solvents and phases can also be exploited to shift the overall distribution ratio K_i between the donor and acceptor solutions. The enrichment factor E can be increased by several orders of magnitude. The thermodynamics of the separation processes enable the attainable maxima of the enrichment and the purification factors to be estimated.

Figure 3 Domain dialysis across a microporous membrane. ϕ , Donnan potential; E, electrodes; U , outer voltage.

Mass Transport

Dialysis For quiescent donor and acceptor solutions the equilibration time ranges from minutes to several hours and is dependent on the geometrical size of the donor and acceptor chambers and the membrane permeability. In this case the equilibration is dominated by the slow diffusional analyte transport. The equilibration can be accelerated by convective mass transport according to Figure 1. Intensive stirring of both the acceptor and the donor solutions establishes diffusional boundary layers of thickness δ on the membrane. The diffusional boundary layer can also be established in flow-through dialysis cells or on rotating dialysis membranes.

The overall flux of the substance i with its molar amount n_i from the donor to the acceptor solution can be described according to eqn [17]:

$$J_i = \frac{dn_i}{dt} = kF \left(\beta_{i,D} c_{i,D} - \beta_{i,A} c_{i,A} \frac{K_{AM}}{K_{DM}} \right) \quad [17]$$

where $\beta_{i,D}$ and $\beta_{i,A}$ are the fractions of the substance i in the donor and in the acceptor solutions respectively, that can permeate through the separation membrane. K_{DM} and K_{AM} are the distribution constants between the donor solution D and the membrane M and between the acceptor solution A and the membrane, respectively. The overall mass transfer coefficient k can be derived from eqn [18]:

$$\frac{1}{k} = \frac{1}{k_D} \left(\frac{k_D \beta_D}{k_D \beta_D + k'_D (1 - \beta_D)} \right) + \frac{1}{k_M K_{DM}} + \frac{K_{AM}}{k_A K_{DM}} \left(\frac{k_A \beta_A}{k_A \beta_A + k'_A (1 - \beta_A)} \right) \quad [18]$$

where $1 - \beta_D$ is the rejected fraction of substance i , $1 - \beta_A$ is the corresponding fraction that is trapped in the acceptor solution, and k_D , k_M and k_A are the mass transfer coefficients of the permeating fractions of substance i for the donor, the membrane and the acceptor phases, respectively. k'_A and k'_D are the mass transfer coefficients for the so-called inactive form of substance i , which cannot permeate the membrane. In many cases the mass transfer across the phase boundary is to be considered additionally, e.g. for homogeneous membranes, supported liquid membranes (SLM) and gas-filled microporous membranes. Then the expression shown in eqn [19] should be added to the right term of eqn [18]:

$$a = \frac{1}{k_{pDM}} + \frac{1}{k_{pAM}} \frac{K_{AM}}{K_{DM}} \quad [19]$$

k_{pDM} and k_{pAM} are the phase transfer coefficients from the donor solution into the membrane phase and from there into the acceptor phase, respectively.

From the general equation some cases of analytical interest can be deduced.

Example 1: Dialysis Through Hydrophilic and Microporous Membranes. Because $\beta_D = \beta_A = 1$, $K_{DM} = K_{AM} = 1$ and no phase transfer takes place, eqn [18] can be simplified to eqn [20]:

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M} + \frac{1}{k_A} \quad [20]$$

For large concentration gradients $(c_D - c_A)/d_M$ and very intensive stirring in the set-up shown in Figure 1 or in flow-through dialysis cells with high flow-rates the membrane diffusional transport becomes rate-determining particularly for relatively thick membranes with small pores. Eqn [21] then follows:

$$k = k_M \quad [21]$$

Example 2: Dialysis of Volatile Substances Through Hydrophobic and Microporous membranes. To separate a nonvolatile base B^- , its corresponding volatile acid BH is produced according to the equilibrium:

The donor pH value is chosen according to eqn [22] so that there is a 99.9% degree of conversion into the permeable form of the analyte:

$$\beta_{i,D} = \frac{10^{-pH}}{10^{-pH} + K_a} > 0.999 \quad [22]$$

K_a is the acid-dissociation constant of BH .

The acceptor pH value should be adjusted according to eqn [23] to trap the analyte in its nonvolatile form:

$$1 - \beta_{i,A} = \frac{K_a}{K_a + 10^{-pH}} > 0.999 \quad [23]$$

Since only the volatile part of the analyte amount can traverse the membrane, it follows that:

$$J_i = kFc_{i,D} \quad [24]$$

with:

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M K_{DM}} + \frac{K_{AM}}{k_A K_{DM}} + a \quad [25]$$

The distribution ratios K_{DM} and K_{AM} are correlated to the concentrations $\beta_{i,D} \times c_{i,1,D}$ and $\beta_{i,A} \times c_{i,1,A}$ of the volatile forms in the donor and in the acceptor solutions, respectively:

$$K_{DM} = \frac{c_{i,g,D}}{\beta_{i,D} c_{i,1,D}} \approx \frac{p_{i,D}}{\beta_{i,D} RT c_{i,1,D}} \quad [26]$$

$$K_{AM} = \frac{c_{i,g,A}}{\beta_{i,A} c_{i,1,A}} \approx \frac{p_{i,A}}{\beta_{i,A} RT c_{i,1,A}} \quad [27]$$

The right-hand terms of eqns [26] and [27] are approximations for low partial pressures $p_{i,D}$ and $p_{i,A}$. $c_{i,g,D}$ and $c_{i,g,A}$ are the concentrations of the analyte in the gas phase at the interface between the donor or the acceptor solution, respectively, and the membrane gas phase. For very small partial pressures $p_{i,D}$ and $p_{i,A}$, $K_{AM} \ll K_{DM}$ ($p_{i,D} \gg p_{i,A}$) and without hydrodynamic transport limitations, eqn [18] can be simplified to eqn [28]:

$$\frac{1}{k} = \frac{1}{k_D} + \frac{1}{k_M K_{DM}} + a \quad [28]$$

For fast-flowing donor solutions with $1/k_D \rightarrow 0$ the mass transport is determined by the gas diffusion through the membrane, the partial pressure of the analyte in the donor solution and the phase-transfer resistances. The partial pressure of the volatile analyte can be increased by decreasing the partial pressure of the water using high ionic strengths in the donor solution. For highly volatile analytes, thin and highly porous membranes, and fast-flowing solutions, the overall mass transport is controlled by the phase transfer resistance ($k = 1/a$).

Reverse osmosis The driving force of reverse osmosis is the difference between the outer pressure p_h and the osmotic pressure difference π . The mass transfer can be described according to eqn [29]:

$$J_L = PF(p_h - f_R \pi) \quad [29]$$

where J_L is the mass flux of the solvent through the separation membrane and P is the water permeability of the membrane. The osmotic pressure difference is multiplied by the reflection coefficient f_R , which is a measure of the solute rejection by the membrane. During the enrichment process in the donor solution the osmotic pressure difference π increases. The driving force decreases. When the rejection is sufficiently high, the reflection coefficient f_R approximates to unity. The rejection ratio is

Figure 4 Reverse osmosis with concentration polarization on the asymmetric separation membrane. J_L , mass flux of the solvent; p_D , outer pressure from the donor solution; p_A , outer pressure from the acceptor solution; π_D and π_A , osmotic pressures of the donor and the acceptor solution respectively; δ_c , thickness of the polarization layer; $c_{i,D}$, solute concentration in the donor solution; $c_{i,DM}$, solute concentration on the membrane; $c_{i,M}$, solute concentration in the separation membrane. See text for further explanation.

defined by eqn [30]:

$$R = 1 - \frac{c_{i,A}}{c_{i,D,0}} \quad [30]$$

where $c_{i,A}$ is the solute concentration in the filtrate, and $c_{i,D,0}$ is the initial concentration in the donor solution. The rejected solutes accumulate on the membrane surface (Figure 4). This is the so-called concentration polarization phenomenon, which can be described approximately according to eqn [31]:

$$J_L = k_L \cdot \ln[(c_{i,DM} - c_{i,A}) / (c_{i,D} - c_{i,A})] \quad [31]$$

where $c_{i,DM}$ is the solute concentration on the membrane surface and k_L is the mass transfer coefficient.

The concentration up to the saturation level will cause the precipitation of the solute. The precipitated solute forms a secondary layer on the membrane, which reduces the solvent mass transfer J_L . Therefore the concentration polarization must be reduced by a forced convective flow.

The analytical usefulness is based on the high enrichment factor E , which can be achieved following by eqn [32]:

$$E = \frac{c_{i,D}}{c_{i,D,0}} = \frac{V_{D,0}}{V_{D,0} - V_A} \quad [32]$$

where $V_{D,0}$ is the initial volume of the donor solution.

Geometric Aspects

The geometric shape and extent both of the donor and the acceptor chambers is decisive for the effectiveness and time of the entire separation process. The geometry has to be adapted to the particular analytical task (Table 1). To minimize the separation time the thickness of the donor solution layer should be as thin as possible. The ratio of the membrane exchange area to the donor solution volume should be maximized. To maximize the enrichment factor for dialysis with enhanced selectivity the volume ratio between the donor solution and the acceptor solution has to be maximized.

In this respect, thin hollow-fibre membranes are especially useful both for enrichment and purification procedures. Thin-layer chambers with flat membranes are also useful and enable a greater variety of different membrane materials to be used. The miniaturization of the membrane exchange area up to the micro or the ultramicro scale enables reproducible sampling from quiescent or slowly flowing solutions to be performed. This is of great importance for *in vivo* sampling with microdialytic probes.

Figure 5 shows frequently used hollow-fibre and flat-membrane set-ups. Table 1 summarizes the most useful procedures for dialysis.

The Separation Membrane

The dialytic transport across thin membranes can be described in eqn [33]:

$$J_i = \frac{dn_i}{dt} = k_M F(c_{i,MD} - c_{i,MA}) \quad [33]$$

$c_{i,MD}$ and $c_{i,MA}$ are the solute concentrations in the membrane at the interfaces with the donor and the

Table 1 Dialysis procedures

Objectives in a microanalytical scale	Donor solution	Acceptor solution
Purification	Quiescent or slowly flowing, small sample volume	Flowing or stirred, large volume

acceptor solutions, respectively. Linear concentration gradients can be assumed in thin membranes.

The separation membrane should be considered particularly with regard to selectivity but also with regard to the overall mass transfer kinetics. The membrane material determines the transport mechanism, which influences the selectivity of the separation process in particular. Table 2 gives an overview about the most important membrane materials and the dominant transport mechanisms. Classic dialysis through microporous membranes causes a loss of sensitivity with respect to the following detection or determination procedure. So-called selective dialysis

across gas-filled membranes or SLMs enables an analyte enrichment to be performed. The selectivity of the SLM technique can be enhanced by the addition of selectively reacting ligands to the liquid membrane phase. When charged ions are complexed and transported through these membrane systems electroneutrality must be maintained. In many cases ion pairs with selected counter ions are transported through the membrane. When the ligand is dissolved in the liquid membrane phase and the counter ion cannot transverse the membrane the analyte ion transport is coupled with a back-diffusion of an ion with the same electric charge. A similar situation can be found in ion-exchange membranes, which are used to enrich ions by Donnan dialysis.

Gas dialysis through hydrophobic and microporous membranes is a fast transport process compared with the other transport mechanisms. The diffusion constants in the gas phase are several orders of magnitude greater than in liquid and solid phases. The selectivity of the membrane transport is determined by the ratio of the partial pressure p_i of the analyte to the total pressure p in the membrane pores. In small pores the condensation and adsorption kinetics of the gases also have to be taken into account.

Gas dialysis across homogeneous membranes is generally more selective. The different solubilities of the gases in the membrane material are additional selection factors. The mass transport rate is considerably smaller than those in microporous membranes.

Applications

Dialysis

Dialysis is mainly used in flow analytical methods to purify, dilute and condition sample solutions. It can also be used to add reagents.

Table 2 Membrane transport and selectivity

Membrane material	Transport mechanisms	Factors which determine the selectivity
Hydrophillic and porous	Diffusion through micropores ($k_M = D_m \epsilon / \zeta d_M$)	Sieve effect
Hydrophobic and porous membranes, filled with an organic solvent	Diffusion through micropores	Solubility and sieve effect
As before, but with selective ligands in the solvent	Diffusion through micropores	Solubility, complexing and sieve effect, co-ion transport
Hydrophobic and gas-filled porous membranes	Gas diffusion and flow	Volatility
Ion exchange membranes	Retarded diffusion through micropores	Ion exchange and Donnan exclusion
Homogeneous and hydrophobic membranes	Solvation and diffusion of gases and hydrophobic solutes with small molecular masses	Solubility in the membrane material

ϵ , Membrane porosity; ζ , membrane tortuosity; d_M , membrane thickness; D_m , diffusion coefficient.

The dialysis module can be placed prior to or in the sample insertion unit, between the sample insertion unit and the reaction/separation zone and also into the detector zone. Figure 5A shows a typical flow-through dialysis cell, which is inserted in many online configurations with liquid chromatography (LC) and flow injection analysis (FIA), e.g. as shown in Figure 6. In Figure 6A the dialysis cell is working continuously. The acceptor stream is connected to the injection valve, which adds the prepurified sample into a nonsegmented carrier flow stream. This configuration is frequently used in LC systems. The sample substances are continuously separated from higher molecular weight substances, precipitations and microorganisms. Therefore dialysis is useful to prevent blocking and prolong the lifetime of the separation column. The continuous dialytic sample pretreatment opens up an effective way to use FIA systems for the online process monitoring of animal cell cultures and other industrial bioprocesses. In many cases food, clinical and environmental samples can be analysed without cumbersome offline sample pretreatment. To circumvent the increased detection limit, which is caused by the inherent dilution, the dialysis cell can be used as a flow-through reactor, in which the analyte is trapped as a more sensitively detectable derivate. The acceptor stream can be stopped for different times to control the reaction time. The separated analytes, e.g. phenol derivatives or aflatoxins, can also be reconcentrated on a solid-phase extraction column, which is inserted into the sampling loop of the injection valve. Also highly specific preconcentration columns, e.g. with immobilized antibodies, can be used.

In Figure 6B the dialysis membrane is contacted only during short concentration impulses with the sample solution. The probability of membrane foul-

ing and clogging is decreased considerably. The sample solution is precisely diluted. This pulsed FIA dialysis is frequently used to adapt ion-selective electrodes, biosensors and miniaturized enzyme reactors to biological sample matrices.

A very promising and expanding field of application was opened up by the so-called microdialysis technique. Miniaturized dialysis probes with tip diameters smaller than 1 mm are implanted into different tissues of living animals for sampling low molecular weight substances from the tissue fluid. The low molecular weight analytes are separated across small membrane (cellulose acetate, cut-off 1000–60 000 Da) windows into a flowing acceptor stream, as shown in Figure 5B. The enrichment factor is controlled by the flow rate ($0.5\text{--}25\ \mu\text{L min}^{-1}$). The microdialysis probes are coupled online to microcolumn LC systems, to capillary FIA set-ups and recently also to capillary electrophoresis devices. In many cases the separated substances, e.g. lactate and glucose, are converted by enzymes which are dissolved together with the cofactors and cosubstrates in the acceptor solution.

Donnan Dialysis

Donnan dialysis across ion exchange membranes is widely used as an efficient suppression technique in ion chromatography. When a cation exchange membrane separates the eluent, which is an aqueous Na_2CO_3 solution, from a reservoir of strong acid, protons are transported into the eluent. Since the membrane is impermeable to anions, the cations from the eluent must diffuse simultaneously into the suppressor reservoir. The chromatographically separated anions are combined with completely dissociated acids, which have a high equivalent conductivity. The CO_3^{2-} ions are converted to the weakly dissociated carbonic acid. In cation chromatography the eluent, e.g. aqueous hydrochloric acid, has to be suppressed. Therefore an anion exchange membrane is used to separate the eluent from a sodium hydroxide suppressor solution. The anions of the eluent are replaced with hydroxide ions to increase the conductivity in the separation peaks and to suppress the eluent conductivity by neutralization to water. Donnan dialysis across ion exchange membranes can also be used to neutralize strong alkaline and acid samples in an online sample pretreatment for ion chromatography.

Donnan dialysis is also used to enrich low molecular weight ions. When a cation exchange membrane separates a high ionic strength solution from a low ionic strength sample solution, cations are transported from the high ionic strength solution to the

low ionic strength solution. Since the membrane is almost impermeable to anions, cations from the dilute solution must diffuse back to the more concentrated solution to maintain the electroneutrality. Anions can be analogously separated by means of an anion exchange membrane.

Ions from dilute solutions, e.g. ground and drinking water samples, can be enriched into high ionic strength solutions with volumes which are smaller than the sample volume. The acceptor solutions can be adapted to whatever determination procedure is to be used. Both flat and tubular ion exchange membranes are used, as shown in Figure 5A,B and D.

Tubular ion exchange membranes with a small inner diameter are particularly useful because of their high surface area to internal volume ratios. Such concentrators can readily be combined with flow analytical set-ups, e.g. flow injection analysis-atomic absorption spectrometry (FIA-AAS) and ion chromatography (IC) systems.

Because of the high osmotic pressure difference between the donor and the acceptor solution and the porosity of the ion exchange membranes a slow water flow takes place, which can be neglected in many analytical applications (Table 3).

It should be noted that the interaction between the diffusing ions and the fixed counterions in the membrane retards the diffusion, which can be accelerated by an alternating electric field with a frequency around 1 MHz. Multiply electrically charged ions, e.g. Mg²⁺ and Al³⁺, decrease the interaction between the sample cations and the fixed counterions, whereby the diffusional transport of the sample cations is accelerated.

Selective Dialysis Across Solid and Liquid Membranes

Selective dialysis is defined here as a separation of substances from an aqueous donor phase into an aqueous acceptor phase, the phases being separated by solid and liquid membranes. The analyte transport through such membranes is based on a solvation/diffusion mechanism in a lipophilic phase. The liquid membranes have to be supported by a microporous and hydrophobic layer to enable practical applications to be performed. Again the basic set-up of the flow separation cells shown in Figure 5 can be used to apply these membranes for separation procedures that can be coupled online to LC, gas chromatography (GC) and FIA set-ups.

Thin silicon rubber membranes can be used to separate e.g. phenols and chlorphenols in a 'push-pull' procedure. The sample solution is acidified to shift the chemical equilibrium to the nondissociated phenol/chlorphenol species, which are dissolved in the silicon membrane. The phenol molecules are trapped as phenolate ions in an alkaline acceptor solution. The maximum enrichment factor is determined by the pH values in the donor and the acceptor solution.

Nonpolar organic substances can also be separated from a sample donor solution into an acceptor solution, but the enrichment factor can only be increased to values greater than 0.5 by addition of an organic solvent to the acceptor solution.

The SLMs have the advantages of faster membrane transport and easier modification of the liquid phase, which determines the transport mechanism and the separation selectivity. Dialysis across SLMs has a wide and growing field of application in

Table 4 Applications of supported liquid membranes

Analytes	Conversion with	Membrane transport	Trapping by	Detection
Mode A

environmental, food and clinical analysis. **Table 4** summarizes some examples of application. Three modes of selective separation are used:

1. The extraction of a hydrophobic substances into the supported organic liquid phase and the following back-extraction into the aqueous acceptor stream.
2. 'Push-pull' separation. The analyte is converted into a membrane-soluble substance, which diffuses through the membrane and is trapped as a substance that is insoluble in the membrane.
3. Co-ion mediated transport on the basis of a carrier substance which is dissolved in the liquid membrane phase. The carrier molecules take up the analyte molecules or ions, whereby a hydrophobic complex or an ion-pair is formed.

Gas Dialysis

Gas dialysis can also be used for FIA procedures and other flow analytical methods to enhance their selec-

tivity. The configurations shown in Figure 5 can be used to separate and enrich volatile or nonvolatile analytes, which can be converted into a volatile substance. **Table 5** gives an overview of the applications of the gas dialysis technique to determine inorganic substances.

The application range can be extended to volatile and water-soluble organic compounds, e.g. lower alcohols (methanol, ethanol, propanol), formaldehyde, acetaldehyde, acetone, ethylene oxide, propylene oxide, ethyl acetate. Several nonvolatile species. e.g. acetate, propionate, can be separated after acidification. Gas dialysis membranes can separate aqueous solutions with very different pH values and ionic strengths, which enables also extreme sample matrices to be adapted to originally unsuitable detection procedures. Microporous PTFE or polypropylene membranes are used in most cases. However, it should be noted that, for example, surfactants and many water-soluble organic compounds can be adsorbed on the membrane surface, which then becomes increas-

ingly hydrophilized. Water penetrates into the membrane pores and changes the mass transfer coefficients considerably with time. In some of these situations homogeneous membranes, e.g. different silicone rubber membranes, can be used to circumvent such interferences. Silicone rubber membranes are permeable to hydrogen sulfide, hydrogen cyanide, carbon dioxide and many volatile organic compounds.

Osmosis and Reverse Osmosis

Diluted sample solutions can be concentrated by both osmosis and reverse osmosis. The concentration process is based on a pressure gradient over a membrane, which rejects the analyte molecules. High molecular weight substances are already rejected by ultrafiltration membranes. But the typical application of reverse osmosis is the separation of low molecular weight substances from aqueous solutions to purify the water or to concentrate the substances which are to be determined.

To concentrate transition and heavy metal ions from dilute aqueous solutions by osmosis the sample solution is separated from a high ionic strength solution by a membrane which is permeable only to the water. An osmotic pressure is built up, which then propels the water into the acceptor (filtrate) solution and concentrates the donor solution. In a thin-layer flow-cell, which is similar to the cell shown in Figure 5A and has a mechanically supported separation membrane (reverse osmosis membrane of cellulose

lose triacetate) preconcentration factors of up to 8–10 for copper(II), cadmium(II), manganese(II), nickel(II) and zinc(II) can be achieved in a countercurrent flow regime.

To implement reverse osmosis, an outer pressure (Figure 2) is applied to propel the water through the membrane. An interesting practical aspect is the possibility of reducing the necessary outer pressure by an osmotic pressure difference which has the same direction. This is implemented by high ionic strength acceptor solutions.

The concentration factor E (eqn [32]) increases considerably with increasing reflection factors (eqn [29]). Highly diluted sample solutions can be concentrated to values that can be determined with the available determination methods. The sample solution can be concentrated up to the precipitation of the solute. Then an additional filter layer is used, which can be exchanged and directly analysed, e.g. by X-ray fluorescence spectrometry. Transition metals could be analysed in drinking water up to the microgram per litre level. Organic contaminants, e.g. chlorobenzene and phenols in alkalized sample solutions, could also be concentrated by reverse osmosis. After this preconcentration traces of the contaminants could be analysed by LC and GC after their redissolution.

Ultrafiltration

M. Cheryan, University of Illinois, Urbana, IL, USA

Copyright © 2000 Academic Press

Introduction

Ultrafiltration (UF) is a filtration process that employs a membrane to fractionate liquid mixtures containing molecules that range in size from about 1000 daltons in molecular weight to 500 000 daltons. The membrane, made of either polymeric or inorganic materials, is a semipermeable barrier containing pores of a certain size distribution that are used to retain or 'reject' components of the feed mixture that are larger than the rated pore size while allowing molecules that are smaller than the pores to pass through the membrane. This separation process is very simple (Figure 1) involving only the pumping of fluids. The membrane is assembled in a particular configuration and placed in a module, and the feed stream is pumped through the module over the membrane surface in a cross-flow mode. The pressure forces solvent

(e.g. water) and solute molecules smaller than the pores on the membrane surface through the membrane into the 'permeate' stream while larger solutes are rejected and retained in the 'retentate' stream. The retentate is recycled through the module until the required degree of purification, separation or concentration is achieved.

Ultrafiltration is similar in concept to other pressure-driven membrane processes such as microfiltration, nanofiltration and reverse osmosis. However, as shown in Figure 2, the size range of the solutes that are retained by each membrane is different. Reverse osmosis (RO) membranes are designed to retain all components except for the solvent (e.g. water). It is essentially a concentration process. Owing to the osmotic pressure of the solutes retained by RO membranes, pressures needed to operate RO systems are typically 30–60 bar (450–900 lb in⁻²). Nanofiltration (NF) membranes have slightly larger pores and are designed to allow monovalent salts such as sodium chloride to pass through, but retains divalent salts, disaccharides and dissociated organic acids. Pressures are usually lower, about 15–25 bar. Microfiltration (MF) membranes retain components that are in suspension or in colloidal form, and is essentially a clarification process. Pressures are usually 1–4 bar.

Ultrafiltration, on the other hand, is designed to retain macromolecules and other solutes in the size range of 1–50 nm, or with equivalent molecular weights of 1000 to 500 000 daltons. It also operates at low pressures (2–6 bar) and can simultaneously act as a concentration, purification and fractionation process, depending on the components in the feed and the membrane properties. It has several advantages over other separation or concentration techniques. Unlike freeze concentration or evaporation, there is

Figure 1 Cross-flow ultrafiltration. Particles in the feed that are larger than the rated pore size of the membrane are retained in the retentate stream while smaller particles pass through into the permeate. (Adapted from Cheryan (1998) with permission from Technomic.)

Ultrafiltration

Introduction

Ultrafiltration (UF) is a filtration process that employs a membrane to fractionate liquid mixtures containing molecules that range in size from about 1000 daltons in molecular weight to 500 000 daltons. The membrane, made of either polymeric or inorganic materials, is a semipermeable barrier containing pores of a certain size distribution that are used to retain or 'reject' components of the feed mixture that are larger than the rated pore size while allowing molecules that are smaller than the pores to pass through the membrane. This separation process is very simple (Figure 1) involving only the pumping of fluids. The membrane is assembled in a particular configuration and placed in a module, and the feed stream is pumped through the module over the membrane surface in a cross-flow mode. The pressure forces solvent

(e.g. water) and solute molecules smaller than the pores on the membrane surface through the membrane into the 'permeate' stream while larger solutes are rejected and retained in the 'retentate' stream. The retentate is recycled through the module until the required degree of purification, separation or concentration is achieved.

Ultrafiltration is similar in concept to other pressure-driven membrane processes such as microfiltration, nanofiltration and reverse osmosis. However, as shown in Figure 2, the size range of the solutes that are retained by each membrane is different. Reverse osmosis (RO) membranes are designed to retain all components except for the solvent (e.g. water). It is essentially a concentration process. Owing to the osmotic pressure of the solutes retained by RO membranes, pressures needed to operate RO systems are typically 30–60 bar (450–900 lb in⁻²). Nanofiltration (NF) membranes have slightly larger pores and are designed to allow monovalent salts such as sodium chloride to pass through, but retains divalent salts, disaccharides and dissociated organic acids. Pressures are usually lower, about 15–25 bar. Microfiltration (MF) membranes retain components that are in suspension or in colloidal form, and is essentially a clarification process. Pressures are usually 1–4 bar.

Ultrafiltration, on the other hand, is designed to retain macromolecules and other solutes in the size range of 1–50 nm, or with equivalent molecular weights of 1000 to 500 000 daltons. It also operates at low pressures (2–6 bar) and can simultaneously act as a concentration, purification and fractionation process, depending on the components in the feed and the membrane properties. It has several advantages over other separation or concentration techniques. Unlike freeze concentration or evaporation, there is

no change in phase of the solvent and thus energy consumption is much lower. Being a nonthermal process, there are no extremes of temperature and feed solutions can be concentrated by UF with little or no thermal damage to heat-sensitive components. Since pores are large enough to allow passage of soluble salts, acids and alkalis, the microenvironment of the solution remains largely unchanged during the process.

There are several factors that affect ultrafiltration applications: the membrane material, properties of the membrane, process engineering parameters, design of the membrane module, fouling and cleaning and process design. The most important performance parameters in UF are flux and rejection. Flux is the volume of permeate per unit time per unit membrane area. Higher flux means lower capital and operating costs. Rejection is a measure of a membrane's separating capabilities. It is defined as:

$$1 - \frac{\text{Concentration of solute in the permeate}}{\text{Concentration of solute in the retentate}}$$

Membrane Material

Membranes have been made from over 150 different polymers or inorganic materials, but only about a dozen have achieved widespread commercial use for UF. The most common are polymers such as polysulfone, polyethersulfone, polyvinylidene fluoride, polyacrylonitrile, cellulose acetate and regenerated cellulose as well as inorganic materials such as alumina, zirconia and titania. Most polymeric UF membranes are asymmetric in structure, i.e. they have a thin 'skin' 0.1–0.2 μm thick on the surface of the membrane. This skin contains the pores of the required size and determines the separation characteristics of the UF membrane. Polymer layers under the skin usually consist of voids which support the skin layer. The skin and void layer are one structure and one polymer when made by a phase-inversion process, but they could be two or more different polymers in composite membranes. The membrane is then laid on a backing such as polyester or polypropylene and then formed into the module. In some cases, such as hollow fibres, a concentrated solution of the polymer is spun or extruded to form self-supporting single polymer hollow tubes with the pores on the inside surface of the tube.

Inorganic membranes have considerably widened the range of membrane applications, particularly in food processing, waste treatment, recovery of chemicals and biotechnology applications, where high temperature, acid and/or alkali stability, steam sterilizability and cleanability are important. A macroporous substrate of a fine dispersion of the powder is first formed, e.g. by thermal sintering of an extruded paste of the powder. If a tubular geometry is used, pastes from two powders of different grain sizes may be co-extruded, with the finer grain being closer to the axis. After baking at high temperatures ($>1000^\circ\text{C}$), the inside may be coated by slip casting with the final fine grain powder. A series of such layers may be necessary to obtain the asymmetric-type ultrastructure. The membrane is finally set by a series of pressurizing, drying and baking steps. The most common ceramic materials are α -alumina, zirconia and titania. Composites of zirconia or titania membranes on alumina, carbon or stainless-steel supports are available.

Most inorganic membranes are available in tubular form, either as a single channel tube or multi-channel element, the latter containing up to 60 individual circular channels, depending on the relative diameters of the channel and the element. The inner diameter of individual channels vary from 2 to 6 mm and lengths from 0.8 to 1.2 m. As many as 99 of these elements may be put together in a single housing, resulting in

8–12 m² per module. Normal process ratings are 15 bar and 150°C.

Inorganic membranes have several desirable properties. They are inert to common chemicals and solvents and have wide temperature limits. Depending on the seals and type of housing, some inorganic membranes can be operated as high as 350°C and within wide limits of pH from 0.5 to 13.5. The biggest advantage is their extended operating lifetimes. Operating life of membranes is most affected by the frequency and nature of the cleaning regime. In contrast to polymeric membranes which typically have 9–18-month lifetimes with normal daily cleaning cycles, inorganic membranes are able to tolerate frequent aggressive cleaning regimes. Many are still operating 10–14 years after installation with the first set of membranes. One major limitation is that they are 10–30 times more expensive than polymeric membranes.

Membrane Properties

Pore size is the most important property of a UF membrane. Pores can be visualized using electron microscopy. Surface porosity (the proportion of the membrane surface occupied by pores) is less than 10% for many UF membranes. In an ideal membrane, all pores should be of the same size. In reality, there is a distribution of pore sizes, as shown in Figure 3. This makes it difficult to get a sharp separation of similarly sized molecules by UF. A common method to characterize UF membranes is to challenge the membrane with several macromolecules of known molecular sizes. Since proteins of different molecular weights are usually used as molecular markers, UF membranes are characterized in terms of their ability to retain proteins of a particular molecular weight. Figure 3 is a graphical representation of solute rejection data for ideal and real membranes. No membrane will display the sharp pore-size distribution shown for the ideal membrane. MF membranes are given 'absolute' ratings which is the largest particle that will be retained by the membrane, based on actual tests under standard conditions. In contrast, UF membranes are given 'nominal' ratings which refer to the molecular weight of a test solute (ideally it should be a globular protein) which is 90% rejected by the membrane under standard conditions. This rating is termed the molecular weight cut-off (MWCO) of the membrane.

Proteins are not ideal compounds to use for this purpose, since their molecular size can be affected by pH, ionic strength and interactions with buffer components. Proteins can have different isoelectric points, solubility and hydrophobicity, thus causing

them to interact with and foul the membrane to different extents, which affects measured rejections. In addition, proteins which differ by 10 times in MW may only differ by three times in size in their globular form. Owing to the difficulty of finding proteins that are sufficiently pure (and inexpensive) to conduct MWCO evaluations, other compounds such as polyethylene glycols (PEG) and dextrans have been used because they are water soluble and can be readily obtained with well-defined and narrow-size distributions. Since the shapes of these various compounds are different, the MWCO profile of a membrane will also differ depending on the solute test marker used. Environmental conditions such as pH and ionic strength also affect shape and conformation of molecules which can affect rejection.

Other components in the feed solution could affect the separation of the target compound. For example, with UF membranes, low-molecular-weight solutes (such as sugars and salts) have molecular sizes much smaller than the smallest pore on the membrane. These compounds will be freely permeable, i.e. they will have zero rejection, unless they interact with or bind to impermeable compounds in the feed. Changes in operating conditions will not affect their permeability. On the other hand, large solutes that are much bigger than the pores will be completely rejected (i.e. 100% rejection). Its rejection properties will also be relatively unaffected by operating conditions or if other compounds are present. However, if the solute has a size that is of the same order of magnitude as the pore, its rejection may be affected in the presence of the large molecule. This is because the large molecule forms a secondary

Figure 3 Typical molecular-weight profile of ideal and real membranes. Relationship shown is between molecular size of a solute in the feed stream and rejection of the solute by the membrane. (Adapted from Cheryan (1998) with permission from Technomic.)

dynamic membrane on the original membrane that inhibits passage of the smaller molecule. Operating conditions that change the shape or conformation of the solute will also affect its rejection.

As a general rule, fractionation of polymers can be accomplished if there is at least a 10-fold difference in molecular weight. Separation of similarly sized macromolecules can be enhanced by diluting the feed to minimize solute-solute interactions and solute-membrane interactions.

Other factors affecting separation are operating parameters such as pressure and cross-flow rate. These control the degree of turbulence and the thickness of the boundary layer and extent of concentration polarization (defined below), which in turn affect permeability of smaller solutes.

Operating Parameters

Separation of solutes by UF membranes occurs by a sieving mechanism. The transport of fluids through the pores is modelled as laminar flow through channels, with flux directly proportional to applied transmembrane pressure. However, it has frequently been observed that under certain operating conditions, flux becomes independent of pressure as shown in **Figure 4**. This is owing to 'concentration polarization' which is shown in **Figure 5**. Molecules or particles that are partially or completely retained by the membrane accumulate on the surface of the membrane during ultrafiltration. This build-up of solids will cause a concentration gradient within the boundary layer, resulting in back-transport of solute into the bulk stream owing to diffusion. Eventually a steady state is reached where the two phenomena balance each other. Solute concentration reaches a maximum at the 'gel concentration'. This con-

Figure 4 Effect of operating conditions on flux of an ultrafiltration system. (Adapted from Cheryan (1998) with permission from Technomic.)

Figure 5 Concentration polarization in ultrafiltration.

solidated gel layer is the reason that pressure independence in **Figure 4** is observed. Flux is no longer controlled by pressure but by the mass-transfer characteristics of the system which in turn depends on the diffusion coefficient of the rejected molecules in the boundary layer, turbulence in the flow channel, viscosity and density of the fluid stream. Higher temperatures lead to higher flux because of its favorable effect on diffusivity and viscosity. In the pressure-independent region, flux decreases in a semi-logarithmic manner with bulk feed concentration and increases with higher turbulence (usually achieved by higher flow rates through the module).

Module Design

There are basically six different designs of membrane modules: tubular (with channel diameters greater than 3 mm), hollow fibre or capillaries (self-supporting tubes, usually 2 mm or less internal diameters), plates, spiral-wound, pleated sheets and moving modules (e.g. rotating discs or cylinders). **Figure 6** shows the more common types of modules. The selection of a particular design depends on (a) the physical properties of the feed stream and retentate, especially viscosity and osmotic pressure, (b) particle size of suspended matter in the feed, (c) fouling potential of the feed stream, and (d) sanitation requirements, such as cleanability and sterilizability. The viscosity of feed streams containing macromolecules such as polymers or proteins will increase nonlinearly with concentration above a certain value. This will require

Figure 6 Schematic of ultrafiltration membrane modules: tubular, plate and spiral-wound.

high pressure drops for pumping and require the use of modules that can withstand high pressures, eliminating most hollow fibre/capillary modules. On the other hand, these modules have extremely high packing densities (surface area : volume ratios) and comparatively low energy consumption, making them useful in applications where the feed is of relatively low viscosity and low in suspended matter.

Spiral-wound modules and some plate modules incorporate a spacer in the feed channel to keep the membrane sandwich apart. This spacer can add considerable turbulence to the fluid flow and thus increase the flux. However, this spacer causes a parasitic drag and creates dead spots in the feed channel, which can cause suspended particles to block the flow channel, resulting in high pressure and cleaning problems.

Fouling and Cleaning

Fouling manifests itself as a decline in flux with time under constant operating conditions. The sieving properties of the membrane may also change. This is owing to irreversible interactions between feed components and the membrane, causing a layer of foulant on the membrane, blinding of the pores and an increased resistance to fluid flow through the membrane. Many membrane materials listed earlier are relatively hydrophobic (e.g. polysulfone, polyvinylidene fluoride) and tend to foul more than hydrophilic membrane materials (e.g. cellulose, cer-

amics). Many feed components interact strongly with membranes, e.g. oils through hydrophobic interactions with hydrophobic membranes, proteins by hydrogen bonding, charge interactions or hydrophobic interactions, and salts by precipitation or charge interaction.

A fouled membrane has to be cleaned according to the nature of the foulant. Proteins can be effectively cleaned with alkaline solutions, salts are removed with acid cleaners. The quality of the water is very important in ensuring a membrane can be effectively cleaned in the shortest time possible.

Flux can be enhanced by periodic backwashing, pulsating flows, uniform transmembrane pressure or co-current permeate flow techniques. These have been found to be effective in maintaining high fluxes with feed streams containing colloidal or suspended matter and less effective with foulants that are in solution.

Applications of Ultrafiltration

Table 1 is a listing of ultrafiltration applications. The food industry has been one of the most successful users of UF, starting from the early 1970s when it was used to treat cheese whey to recover the protein. Another successful application has been electrocoat painting, where the UF system is used to maintain the ionic balance of the painting system and to recover paint that has been washed off. Biotechnology has benefited tremendously by UF, where it finds its greatest use in the production of pyrogen-free water and for fractionation, purification and concentration

Table 1 Applications of ultrafiltration

<i>Food industry</i>	
Concentration of protein and fat for cheese manufacture; fractionation of cheese whey for whey protein concentrates; clarification of fruit juices (apple, apricot, citrus, cranberry, grape, peach, pear, pineapple); gelatin concentration and de-ashing; eggs concentration and reduction of glucose; animal blood concentration; soybean protein concentrates and isolates; clarification of protein hydrolysates; vegetable oils (degumming, deacidification, bleaching, removal of metals, dewaxing; clarifying frying oils); sugar refining; dextrose clarification; alcoholic beverages	
<i>Chemicals and wastewater</i>	
Electrocoat paint; oily wastewater; stillage from bioethanol plants; caustic and acid recovery; brine recovery; printing ink; laundry wastewater; textile industry; latex emulsions; pulp and paper industry; tanning and leather industries; fish processing; poultry industry	
<i>Biotechnology</i>	
Separation and harvesting of microbial cells; enzyme recovery; affinity ultrafiltration; membrane bioreactors	

of proteins and other macromolecules. Continued advances in membrane science and manufacture and engineering improvements to modules and systems will allow a greater penetration of this technology in a variety of industries in the future.

PARTICLE SIZE SEPARATION

Electrostatic Precipitation

Introduction

Electrostatic precipitators (ESPs) are the most commonly used devices for the removal of fine particles in exhaust from industrial and utility processes. Wire-plate ESPs consist of three or more sections of arrays of large (e.g., 15 m × 5 m), grounded metal collector plates between which are situated wire or other narrow, high voltage electrodes (Figure 1). Less commonly, a wire-cylinder electrode configuration is used. Particles entering the first section are quickly charged by ions generated by the plasma coronas around the wires. (Current does pass between the

electrodes, hence the term ‘electrostatic’ is not really accurate, but indicates the small current-to-electrode area.) The charged particles are drawn toward and deposit upon the collector plates, which are periodically cleaned by mechanical ‘rapping’. This method is very efficient in removing particles in the 1–>10 μm range. The most common use of ESPs is in control of exhaust from coal combustion utilities. Precipitators are also used in the cement, ore smelting, steel production, pulp and paper manufacturing, and chemical processing industries, and in waste combustion utilities. Small units are used in cleaning domestic and workplace air, and have been considered for use in animal production facilities.

M. Holfield first demonstrated the removal of particles by electrostatic charging in 1820. Holfield showed that tobacco smoke can be cleared in a bottle by applying a spark-producing voltage to a pointed electrode inserted in the bottle. In 1850, C. F. Guitard observed that a steady corona discharge is effective in dissipating smoke. Sir Oliver Lodge first attempted

Figure 1 Rigid frame electrostatic precipitator. (Reproduced with permission. Copyright Wheelabrator Air Pollution Control Inc.)

the commercial application of this phenomenon by constructing an electrostatic precipitator to control fumes at a lead smelter. Unfortunately, lead oxide is too resistive to allow sufficient particle charging with a constant DC discharge, and the application failed. The first successful commercial application of electrostatic precipitation was by F. G. Cottrell, who designed an ESP to remove acid mist from sulfuric acid plants. Cottrell facilitated the establishment of the technique by developing the first suitable high-voltage power supplies. ESP particle control became widely used between 1910 and 1930.

Removal of small particles from gas streams is important for process, health, and environmental reasons. Centrifugal separators are used to remove particles larger than $10\ \mu\text{m}$; fabric filter 'baghouses' are used to remove finer particles and constitute a viable alternative to ESPs. Capital costs are similar for baghouses and ESPs; however, maintenance, including energy cost, is lower with ESP units.

The increased control of sulfur and nitrogen oxides in the 1970s, and recent calls for the control of very fine particles, challenge scientists and designers concerned with the ESP technique. Use of low sulfur coal reduces fly ash resistivity below that appropriate for conventional ESP operation. Treatment by the addition of limestone to coal increases the particle load on precipitators. Conventional precipitators do not efficiently remove submicron particles. As will be discussed in this chapter, researchers are developing means of adapting ESP design and opera-

tion to meet the challenges of improved environmental control.

Characteristics of Fly Ash

Hart *et al.* recently performed a comprehensive investigation of the composition and mineralogy of fly ash from three utility boilers. Using instrumental neutron activation analysis and X-ray fluorescence spectroscopy, they found Si, Al, Fe and Ca to account for more than 90% of major elements from all three boilers. Scanning electron microscopy with energy dispersive spectroscopy revealed successive ESP ashes to be composed mainly of spherical particles which decrease in average diameter with increasing distance from the boiler. Concentrations of As, Co, Cr, Ni, Mo and Sb increased from bottom ash through the sequence of ESP ashes. These trace elements are volatilized and transported to cooler regions, where they condense or are adsorbed onto fly ash particles. The major fly ash mineral phase found by these and other researchers is quartz (SiO_2) with magnetite (Fe_3O_4), anhydrite (CaSO_4), and mullite ($\text{Al}_6\text{Si}_2\text{O}_{13}$) among other minerals commonly present.

Resistivity (ρ) is the most important property of material to be collected by an ESP. The optimum range of resistivity is 10^4 – $10^{11}\ \Omega\text{-cm}$. On collection, low resistivity particles ($\rho \leq 10^3\ \Omega\text{-cm}$) release charge to the collector plate and may be re-entrained. Particles with $\rho > 10^{11}\ \Omega\text{-cm}$ insulate the collector plate, ultimately producing a sufficiently large electric field

within the dust layer to cause a counterproductive 'back corona'.

Two types of resistivity may be important in particle collection in an ESP. Ions collected at the surface of particles control 'surface resistivity', which dominates at temperatures below 250°C. As indicated in Figure 2, particle resistivity first increases with temperature, then decreases. Removal of the surface film (adsorbed water) by heating *in vacuo* at 360°C eliminates this initial increase in resistivity. Above 200°C, removal of adsorbed material no longer affects resistivity, and at higher temperatures resistivity is attributed to ions in the bulk of the particles,

'volume resistivity'. Both types of resistivity are primarily functions of Na^+ and Li^+ ion concentrations, and in some cases K^+ and I^- ions.

Two aspects of the ρ - T relationship affect ESP collection efficiency. First, the maximum resistivity of fly ash occurs within the range of temperature at which ESPs are commonly operated, 130–180°C. Second, SO_3 , produced from sulfur in coal, adsorbs onto the fly ash particles and has traditionally been responsible for lowering the resistivity of the particles to the optimum range for collection. Present use of low sulfur coals (<1% S) leads to inadequate collection.

Figure 2 Effect of surface film resistivity on flue-dust resistivity. (Reproduced with permission from Busby HGT and Darby K (1963) *Journal of the Institute of Fuel* 36(268): 184. Copyright The Institute of Fuel).

Operation at non-optimal temperature can be avoided by lowering the temperature, but this requires energy input to a cooling device, and also can lead to difficulties with corrosion due to condensation. The temperature of the exhaust is normally cooled by heat exchange in an air pre-heater prior to injection into the precipitator, hence the name 'cold-side' precipitator. 'Hot-side' precipitators operate at temperatures as high as 370°C; resistivity is often reduced to a desirable level of $2 \times 10^{10} \Omega\text{-cm}$ at above 315°C. However, difficulties are encountered with the greater volume of the hot gas, and these units require more careful construction.

More commonly, resistivity of high-resistance ash is lowered by chemical conditioning.

Theoretical and Practical Aspects of Electrostatic Precipitation

Charging of Particles

The corona surrounding a discharge electrode of an ESP is a gas plasma of electrons and cations. The cations are drawn into the electrode, which is biased negative. The electrons are repelled into the interelectrode space where, within one centimetre travel, they ionize gas particles. These gas particles are drawn toward the grounded collector electrodes. On the way, many of them collide with and attach to the particles to be collected, charging them. The charged particles are then drawn towards the collector electrodes. This particle charging is efficient. Typical charging time is 5 ms; typical residence time in an ESP is 2–5 s.

Charging processes are of two types: field charging, where ions moving with the electric field charge the particles, and diffusion charging, where charging is due to collision with ions moving with random thermal motion. The types are distinguished to facilitate mathematical description. Field charging is dominant in charging particles with radius (a) greater than $0.5 \mu\text{m}$; diffusion charging is dominant with $< 0.2 \mu\text{m}$ particles. Both mechanisms are important in the intermediate size range.

The charge on an ion at time t ($q(t)$) resulting from field charging, derived by Pauthenier and Moreau-Hanot is:

$$q(t) = 12 \frac{\kappa}{\kappa + 2} \pi \epsilon_0 a^2 E_0 \frac{t}{t + \tau}$$

where κ is the relative dielectric constant; ϵ_0 is the permittivity of free space ($\text{C}^2 \text{N}^{-1} \text{m}^{-1}$); a is the particle radius (m); E_0 is the electric field (V m^{-1}); t is the

time (s) and:

$$\tau = 4\epsilon_0/N_0eb$$

where N_0 is the number density of particles (m^{-3}); e is the electronic charge (C); b is the ion mobility ($\text{m}^2 \text{s}^{-1} \text{V}^{-1}$). (This and other formulae are in the form presented in Oglesby and Nichols (see Further Reading.) The corresponding expression for diffusion charging presented by White is:

$$q(t) = \frac{akT}{e} \ln \left(1 + \frac{\pi av N_0 e^2 t}{kT} \right)$$

where k is the Boltzmann's constant (J K^{-1}); v is the rms thermal velocity of ions (m s^{-1}); T is the absolute temperature (K).

Smith and McDonald derived an expression for combined diffusion and particle charging. They divided the surface of a particle being charged into three regions: region I, where the electric field of the particle and that within the ESP duct intersect, sweeping ions onto the particle surface; region II, where the radial component of the electric field of the particle dominates; and region III, where the electric field of the particle and duct are in the same direction, sweeping ions away from the particle. Giving the electric field about the particle, E_r , as:

$$E_r = E_0 \cos \theta \left(1 + 2 \frac{\kappa - 1}{\kappa + 2} \frac{a^3}{r^3} \right) - \frac{ne}{4\pi\epsilon_0 r^2}$$

where E_r is the radial component of electric field (V m^{-1}); E_0 is the external field (V m^{-1}); r is the radial distance to point of interest (m); θ is the azimuth angle measured from the z axis (toward the discharge electrode) (rad); ne is the particle charge (C); these researchers produced a combined charging rate equation:

$$\begin{aligned} \frac{dq}{dt} &= \frac{dq}{dt_I} + \frac{dq}{dt_{II}} + \frac{dq}{dt_{III}} \\ &= (N_0 A n_s e^2 / 4\epsilon_0) \left(1 - \frac{n}{n_s} \right)^2 \\ &\quad + \frac{e\pi a^2 v N_0}{2} \int_{\theta_0}^{\pi/2} \exp \left[- \left(\frac{ne^2(r_0 - a)}{4\pi\epsilon_0 k T a r_0} \right. \right. \\ &\quad \left. \left. + \frac{[3ar_0^2 - r_0^3(\kappa + 2) + a^3(\kappa - 1)]eE_0 \cos \theta}{k T r_0^2(\kappa + 2)} \right) \right] \sin \theta d\theta \\ &\quad + \frac{e\pi a^2 v N_0}{2} \exp(-ne^2/4\pi\epsilon_0 a k T) \end{aligned}$$

Figure 3 Modes of particle charging. —♦—, field charging; —■—, diffusion charging; —▲—, total charge; —×—, Boltzman charge AC. (Data from Kanazawa *et al.* (1993) *Journal of Electrostatics* 29: 193. Copyright: Elsevier Science.)

where A is the surface area of the particle on which ions may impinge (m^2); n_s is the saturation charge; θ_0 is the greatest angle of region from z axis (rad).

This expression agrees well with measured charging rates.

Representative saturated particle charge as a function of particle radius is presented in Figure 3.

Chemical Conditioning

Conditioning can enhance collection efficiency by reducing resistivity to prevent back corona, increasing cohesivity of the collected layer, enhancing the electric field by increasing the space charge contribution (see below), and increasing agglomeration of small particles. Some exhaust gas conditioning methods which have been used to enhance ESP performance are cooling by in-leakage of cold air, heat exchange to a waste heat boiler, evaporative spray, and chemical

conditioning. The latter has proven most popular in utility applications.

Most commonly, sulfur is combusted and the SO_2 produced is catalytically converted to SO_3 . On combination with the combustion exhaust, SO_3 hydrolyses to produce H_2SO_4 , sulfuric acid. The acid deposits efficiently on fly ash particles, decreasing the particle surface resistivity. SO_3 is added at levels of 1–10 ppm; up to 30 ppm can be added without significant increase in sulfur emission from the ESP. Significant SO_2 is produced on combustion of even low sulfur coal, but only about 1% is converted to the useful SO_3 . Knowledge of the importance of SO_3 was initially gained through experience with conditioning of smelter dusts by sulfide ores.

Ammonium salts were found to be effective when H. J. White was consulted on the problem of decreased ESP efficiency which resulted from a change in petroleum cracker catalyst. He found that replacing ammonia, released by the initial catalyst,

recovered ESP performance. As NH_3 increases collection efficiency with both low and high resistivity boiler ash, and may or may not decrease resistivity, it is thought that this conditioner functions by furnishing salt particles which increase the space charge contribution to the electric field and, by increasing dust cohesiveness, reduce rapping losses.

Characteristics of the Corona Discharge

As voltage applied to a wire discharge electrode is increased, visible discharge points, 'tufts', begin to appear dispersed along the wire. Eventually the tuft pattern stabilizes, appearing as fingers which elongate and retract at 1–10 Hz and remain at somewhat fixed locations along the wire. This stabilization of the corona is indicated by a distinct increase in the slope of the electric field vs. applied voltage curve (Figure 4). Peek determined a semi-empirical expression for the corona onset voltage (V_c) in air:

$$V_c = 3 \times 10^6 am\delta(1 + 0.03\sqrt{\delta/a})\ln(b/a)$$

where V_c is the corona onset voltage (V); a is the radius of discharge electrode (m); m is the wire roughness factor (0.5–0.9); δ is the relative air density; P is the air pressure (Pa).

This discharge produces a current density (with respect to the area of the collector electrode) in the order of 150 nA cm^{-2} . While the ionic composition of the interelectrode space has not been well studied, ionization properties indicate that this current is carried by oxygen, sulfur dioxide, and water, which are negatively charged by the electron current

Figure 4 Electric field on the collector electrode just under the corona wire as voltage is applied; d , discharge electrode diameter. $2D = 20 \text{ cm}$; \circ , $d = 0.5 \text{ mm}$; \triangle , $d = 0.71 \text{ mm}$; \square , $d = 1.09 \text{ mm}$. near the corona, and by particles ionized by these primary ions.

The Electric Field

Current vs. voltage curves (Figure 5) are commonly used in monitoring the operation of ESP. For best collection efficiency, ESP units are operated at the maximum voltage which produces a stable current. A discussion of operation monitoring of ESPs is given by DuBard and Nichols.

Much effort has been given to the task of determining the electric field within an ESP. Besides the burden of inability to solve known expressions analytically for the field in a wire-plate electrode system, this task is made difficult by uncharacterized changes in the collector electrode as the dust layer collects on it. The advent of high-speed computing has allowed satisfying solution of the field equations for a clean system.

Cristina *et al.* present a modern method of determining the electric field. These researchers use the following expressions for charge and electric potential:

$$\nabla \cdot (\epsilon \nabla \phi) = -Q$$

$$\nabla \cdot (Q \nabla \phi) = 0$$

where ϵ is the permittivity of air ($\text{C}^2 \text{ N}^{-1} \text{ m}^{-1}$); Q is the ionic charge density (C m^{-2}); ϕ is the electrical potential (V).

These equations have a unique solution for DC ion flow fields. An iterative numerical procedure

is used to balance the electric field and charge density of elements in an array of triangular elements superimposed on the inter-electrode space. These elements are each specified to have a constant ionic charge density. The contribution of space charge by ionized particulate matter is disregarded in this treatment. In the more dust-laden regions of an ESP, particulate matter is found to alter electric field slightly.

Equipotential field maps developed by this treatment show a fairly linear decrease in potential from the discharge to the collector electrode, with circular fields to about one-third distance across the channel (from 57.5 kV to 20 kV), then equipotential field lines parallel to the collector. Near the collector electrode, at about five-sixths the channel width, the potential has decreased to 5 kV. Electric fields of adjacent discharge electrodes interact, producing bell-shaped electric field patterns radiating from each wire to the adjacent collector plates.

Back Corona

In working ESPs, a portion of the applied potential is dropped across the resistive layer of the collected dust. As the dust layer thickens the resistance, hence voltage drop, across the layer increases. If the dust resistivity is high ($\rho > 10^{10} \Omega\text{-cm}$), eventually the field becomes great enough to cause electrical breakdown of gas within the dust layer, generating a back corona. Electrons are ripped from the gas, and the resulting positive ions flow into the inter-electrode space, where they attach to negatively charged particles. The diminished net charge of the particulates leads to greatly diminished collection efficiency; re-entrainment also occurs. A back corona occurs with an electrical field strength across the dust layer (resistance of layer times current) of $8\text{--}12 \text{ kV cm}^{-1}$.

A back corona can be visually observed as a glow on the collection surface. It is also characterized by an increase in corona onset voltage followed by an increase in current for a given applied voltage as compared with a correctly functioning system (Figure 5). The dust layer acts as a resistive-capacitative element in having a lag time before discharge. Both intermittent and pulse energization take advantage of this lag time to allow the application of high voltage without the occurrence of back corona.

Current Density

The electric field at ESP collection surfaces is not uniform due to both the electrode-collector geometry and to irregular resistance resulting from uneven dust layer thickness. The parameter determined in studying the situation at the collection surface is current

density, j (nA cm^{-2}). With poor distribution of current over the dust layer, collection efficiency is diminished. Re-entrainment can occur in regions of low current density, and high local currents can lead to back corona even with a low average current. Landham *et al.* measured the current density distribution in a pilot scale ESP by inserting a segmented copper electrode sensor board into a collector electrode. Conventional, intermittent, and pulse energization with both wire and barbed-strip discharge electrodes were investigated. (Barbed-strip electrodes are used by some manufacturers to force a more uniform current distribution at the collector.)

Intermittent energization (IE) is achieved by interrupting the rectifier circuit output for one to twenty half cycles of the supply power line. A baseline voltage is maintained, with relatively broad pulses superimposed. In pulse energization (PE), pulses of $1 \mu\text{s}$ to 1 ms width and up to -75 kV are superimposed on a DC voltage set just below the 'spark limit'. Both techniques have been found to save energy and to reduce the incidence of back corona. PE is more effective in countering problems with low resistivity dust. Dubard and Nichols set IE to one full AC cycle on and four off (duty cycle 0.2), and PE base voltage -20 kV with 50 Hz , $\sim 125 \mu\text{s}$ width pulses of -25 kV . Conventional full-wave rectified energization (CE) was set at about -35 kV .

These researchers found that CE and PE give Gaussian current density profiles across the sensor plate surface, while IE gives a more even, but lower magnitude distribution. Under good operating conditions (clean collector surface), PE had less collector area above dust layer breakdown current than CE or IE, with 96% useful area as compared to 83% and 86%, respectively. Under severe back corona conditions, PE maintained 84% useful area, CE 12%, and IE 54%. Similar results were obtained with both barbed-strip and wire electrodes. The results indicate a linear relationship between the increase in collector area receiving useful values of current density and collection efficiency.

Among alternative discharge electrode designs, barbed plate discharge electrodes appear more effective in producing uniform current distributions (see McKinney and Davidson). This design may also have some advantage with respect to flow turbulence.

Flow

Besides electric field and current density distribution, gas flow is important in ESP performance. ESP flow velocities vary between 0.2 and 2.0 m s^{-1} . Schwab and Johnson suggest an optimum velocity of between

1.22 and 1.52 m s⁻¹. Lower velocities diminish the turbulent mixing which brings small particles into the low flow region near the collector electrode; higher velocities overwhelm electrostatic attraction of particles to the collector electrode, and can lead to re-entrainment.

Flow within an ESP is inherently turbulent due to high gas flow velocity, which typically results in a Reynolds number of about 10 000 – five times that at which turbulent flow replaces laminar flow. Turbulence in ESPs is complicated by flow obstructions – discharge electrodes and collector stiffening baffles and connectors, and by a non-uniform flow profile at the ESP inlet. At low velocities ($\lesssim 0.5$ m s⁻¹) turbulence resulting from the ion current between discharge and collector electrodes (ionic wind) contributes significantly. The flow regime in an ESP is thus seen to be quite complicated. Baffles within the ESP duct and porous plates at the inlet and outlet are employed to create uniform flow.

Schwab and Johnson have produced a computer model based on Navier–Stokes fluid flow equations as an alternative to traditional reduced scale physical models for flow design. The model can be used to determine inlet plate perforation patterns which produce uniform flow without high flow near the duct walls.

Collection Efficiency

Most important in ESP operation is the particulate collection efficiency, η , the fraction of particulates removed. Around 1920, Deutsch and Anderson independently derived an expression for η , now commonly referred to as the ‘Deutsch equation’:

$$\eta = 1 - \exp\left(-\frac{A}{Q} \omega_e\right)$$

where A is the collector electrode area (m²); Q is the volumetric gas flow rate (m³ s⁻¹); ω_e is the effective particle migration velocity (m s⁻¹).

Efficiency is also expressed as fractional particle penetration, $P = 1 - \eta$. A/Q is the specific collection area (SCA), the parameter of importance in sizing an ESP. Assumptions of the Deutsch equation are that particles are instantaneously fully charged and accelerated, turbulent and diffusive forces cause particles to be distributed uniformly in any cross section of the precipitator, the velocity of the gas stream does not affect the migration velocity of the particles, particle motion is governed by viscous drag where Stokes’ Law applies, the effect of collision between ions and neutral gas molecules can be neglected, and there are

no disturbing effects such as erosion, re-entrainment, uneven gas flow distribution, sneakage, or back corona. A number of researchers have adjusted the Deutsch equation to account for neglected factors. Especially questionable is the assumption of complete turbulent mixing (for instance, see Zhibin and Guoquan). The Deutsch model represents one mixing extreme, with the other extreme being laminar flow (no turbulence). The Deutsch model tends to underestimate η for particles with diameter less than about 1 μ m, and overestimates the collection of larger particles.

The Matt–Öhnfeldt modification attempts to account for variation in particle size distribution:

$$\eta = 1 - \exp\left(-\frac{A}{Q} \omega_k\right)^m$$

where ω_k is the particle migration velocity (m s⁻¹); m is an exponent which depends on particle size distribution.

An m of 0.5 is commonly used with fly ash or cement dust; increasing values can be used with finer size distributions.

In comparing ESP performance under varying conditions, the migration velocity is more useful than η , being independent of ESP collection area and gas flow rate. An important consideration in using ω values is that migration velocity of large particles decreases at a much lower rate with increasing gas flow (or decreased plate size) than that of small particles, hence though small particles will be less efficiently collected, measured ω can increase with gas flow rate.

Migration of charged particles can be treated theoretically. Hall presents the expression:

$$\omega = \frac{4\pi\epsilon_0 k a E_0 E_p C D f}{6\pi\eta} \alpha$$

where k is $3\epsilon/(\epsilon + 2)$; ϵ is the dielectric constant of ash (C N⁻¹ m⁻¹); E_0 is the particle charging electric field strength (V m⁻¹); E_p is the particle collecting electric field strength (V m⁻¹); a is the particle radius (m); C is the Cunningham slip correction; D is the factor to account for diffusion charging of fines; f is the factor accounting for gas turbulence and free electron charging; η is the gas viscosity (Pa s); α is the fractional particle saturation charge.

C is used to adjust diffusion of particles with size comparable to mean-free path of gas molecules. The reader can understand that empirical estimation of ω values, from measured efficiency, is often more productive than theoretical estimation.

The Deutsch model is often used in determining a minimum specific collection area in sizing precipitators. Extrapolation from performance of pilot or other ESPs should be made only with similar designs and similar dusts.

Computer Modelling

Several comprehensive models of particle collection in wire-plate ESPs are available, including the Southern Research Institute (SRI), Research Triangle Institute Sectional (RTIS), Italian Electricity Board (ENEL), and Electric Power Research Institute (ESPM) models. As an example, the ESPM model will be briefly described (see Lawless and Altman).

In ESPM, the applied voltage for a given current density is first determined for a position directly beneath the wire:

$$V = V_c + E_c r_w \left[z - 1 - \ln \left(\frac{z+1}{2} \right) \right]$$

where E_c is the electric field at wire surface at corona onset (V m^{-1}); r_w is the radius of wire (m) and:

$$z = \sqrt{1 + \frac{j b}{\mu \epsilon_0} \left(\frac{b}{V_w} \right)^2}$$

where b is the wire-plate separation (m); μ is the ion mobility ($\text{m}^2 \text{s}^{-1} \text{V}^{-1}$).

Current densities at other plate locations are calculated as:

$$j(\theta) = j_0 \cos^n(\theta)$$

where θ is the angle from between wire and plate (rad); n is a function of j , 2 (near corona onset) to 4.

Ion mobility is based on that of SO_2 and SO_2^- . Space charge resulting from the charging of particles is treated as an equivalent ion current and used to adjust the operating voltage.

Non-dimensional parameters are used in models to add generality to results and to simplify mathematical treatment. For instance, the initial particle charging rate in an ESP model (ESPM), combining both diffusion and field charging, is:

$$\frac{dv}{d\tau} = \frac{3w}{4} \left(1 - \frac{v}{3w} \right)^2 + 1$$

where v is the non-dimensional charge; τ is the non-dimensional exposure time; w is the non-dimensional electric field.

Intermediate and saturation charging rates are modelled by different expressions. Back corona charging can be modelled with ESPM, though better understanding of this process is needed to assure accurate results.

Particle collection is modelled with a modified Deutsch expression:

$$P = \left(1 - \frac{\omega A/Q}{Nw} \right)^{Nw}$$

Nw is a parameter to adjust for turbulence: a high value approaches Deutschian total mixing, a low value approaches laminar collection (laminar when $Nw = 1$). To correct for uneven gas flow, penetration is calculated at several gas velocities and the results combined by weighted averaging. Rapping loss can be specified or estimated by applying conventional dynamics to the falling of agglomerated 'cake' during collector cleaning. The model treats each ESP section separately, 'remixing' particulates exiting from each section.

ESPM can be used to predict V-I curves, 'grade efficiency' (penetration as a function of particle diameter), and other aspects of ESP performance under varying conditions.

Innovative ESP Designs

Several new means have been developed to facilitate collection of submicron and highly resistive particles by ESPs.

Pulse energization is discussed above (see Current density). By superimposing a brief, high voltage pulse on a DC voltage set just below the back corona level, efficient fine particle charging and collection are obtained with highly resistive dusts.

Enhanced particle agglomeration can also facilitate fine particle collection. For instance, Kanazawa *et al.* have accentuated particle agglomeration with a precharging section, in which the gas stream is divided and particles in the two sub-streams given either a positive or a negative charge. On recombining the sub-streams, particles agglomerate through electrostatic attraction. Watanabe *et al.* have devised an alternative method utilizing a three sector design. Large particles are removed in the first ESP sector. A 'modified quadrupole' electrode system in the second sector applies an AC field to enhance particle collision, hence agglomeration. The third section is again a conventional ESP, which removes the agglomerated particles.

Fabric filtration is the surest means of removing fine particles. EPRI has devised the 'Compact Hybrid Particulate Collector' (COHPAC). This design simply places a baghouse after an ESP. The ESP removes much of the particulates, easing the load on the baghouse, hence reducing maintenance. The baghouse reduces pollution due to rapping loss, and is insensitive to changes in fuel.

EPRI has also developed an 'EPRICON' process which can replace conventional chemical conditioning of fly ash from low sulfur coals. In this process, a portion of the gas stream is diverted to a vanadium oxide-based catalytic unit, which efficiently converts SO_2 to SO_3 . Recombination of the treated stream with the bulk results in the necessary conditioning of the fly ash.

Field Flow Fractionation: Electric Fields

S. N. Semenov, Institute of Biochemical Physics,
Russian Academy of Science, Moscow, Russia

Introduction

Field flow fractionation (FFF) represents a class of separation techniques, which use a force field perpendicular to the direction of separation to control the longitudinal velocity of particles injected into the system. It is achieved by particle redistribution in the flow with a parabolic velocity profile due to the action of a transverse force. This transverse force may be due to an electric field, a centrifugal or gravity field, etc. In electric FFF (ElFFF), the transverse movement of the particles is caused by an electric field. The transverse particle velocity, U , is defined by

the expression:

$$U = b \cdot E \quad [1]$$

where b is the particle electrophoretic velocity, and E is the electric field strength in the channel interior, which is available both for the particles and the flow of the carrier liquid. The particle electrophoretic mobility is related to the particle electrokinetic potential (zeta-potential):

$$b = \frac{\varepsilon \zeta}{4\pi\eta} f\left(\frac{R}{\delta}\right) \quad [2]$$

where ε is the dielectric constant of the carrier liquid, η is the carrier liquid viscosity, ζ is the particle electrokinetic potential, R is the particle diameter, and δ is the Debye length characterizing the screening

of the electrostatic interaction in an electrolyte. $f(R/\delta)$ is a function changing monotonously from 1 for particles of $R \gg \delta$ to 1.5 for small particles, when the zeta-potentials are small. For higher zeta-potentials, this function approaches a minimum of less than one. Thus, the particle electrokinetic potential and electrophoretic mobility represent the parameters slowly changing with the particle size and depending mainly on the surface properties of the particle. For small objects like macromolecules and low-molecular-weight ions, the theory of the electrophoretic mobility is absent.

For the characteristic relaxation time, the Boltzmann transverse particle distribution is established in the system by forcing injected particles toward the wall of the channel and their thermal (diffusion) motion. In EIFFF (reported as the method for protein separation), particles of the same size with higher electrophoretic mobility or zeta-potential will accumulate more closely to the wall, while particles of lower zeta-potential will form a more diffuse layer that extends further into the flow of the carrier liquid. Proteins still represent most of the EIFFF sample materials. For particles with about the same zeta-potential, the thickness of this layer may also be different, if the particles have different diffusion coefficients, D . Particles with higher diffusion coefficient (i.e., with smaller size) will accumulate in a more extensive layer due to more intensive thermal movement. Zeta-potential is an important parameter interrelated to the particle surface charge density, and characterizing the particle surface properties and the possible exchange of substances between the particle and the surrounding liquid, e.g. in cellular processes, including transport through cell membranes, antigen-antibody interactions, and hormonal control.

EIFFF is carried out in a thin channel of rectangular cross-section with the width to thickness ratio (aspect ratio) about 100 (thickness about 10–100 microns). It allows the separation to approximate to a laminar liquid flow between infinite parallel plates, which is characterized by a parabolic velocity profile, where the fluid velocity at the channel walls is zero and reaches a maximum in the centre of the channel. Thus, if a group of particles maintain an average distance from the wall different from another group of particles, their velocities along the channel will be different and they will leave the channel at different times, related to the particle zeta-potential and size, which defines the particle diffusion coefficient. In FFF systems, the same types of fields are used as in the so-called 'direct field methods' (centrifugation, electrophoresis, etc.), but there is no requirement of complete fraction resolution in the field direction, and

field strengths may be lower. In principle, all mixtures separated by direct electrophoresis may be effectively analysed by EIFFF, if they have a size large enough to form a layer of thickness smaller than the channel thickness, even when its electrophoretic mobility is too small for electrophoretic analysis. FFF systems are elution methods and allow the collection of fractions during a separation. Since the theory of FFF dynamics is well developed, the separation times for a given sample can be directly related to the physical parameter of the particles. This parameter represents the effective particle charge q^* , which defines the thickness of the Boltzmann particle distribution $\approx \exp(q^*E \cdot x/kT)$ (x is the transverse coordinate in the channel) in the transverse electric field applied to the EIFFF channel. Using the known Einstein relationship, this effective particle charge may be defined as the ratio of the particle electrophoretic mobility multiplied by the thermal energy kT , to its diffusion coefficient:

$$q^* = kT \frac{b}{D} \quad [3]$$

In principle, this effective charge itself represents a new separation parameter, which may be used for particle and macromolecule characterization, if the theory is developed. This theory should relate the effective charge and the particle and macromolecule physicochemical parameter important in specific applications, for example, the surface density of charged groups raised in dissociation or ion adsorption. In turn, this effective charge could be used for the electrophoretic mobility or zeta-potential determination, if the particle diffusion coefficient is determined independently, and the system temperature is known. Another possibility is to separate particles with the same surface properties (i.e. zeta-potentials) but different sizes, where the sample selectivity is only due to the differences in diffusion coefficient. Of course, the real applications of EIFFF are defined by specific experimental conditions, opportunities and advantages rather than by method theory, but, without a clear physicochemical understanding of macromolecule and particle behaviour in EIFFF, the method applications will be very limited.

A focusing (or hyperlayer) mode of operation using isoelectric focusing in a pH gradient across the channel has been reported by a number of authors (see Further Reading) with a channel of trapezoidal cross section. However, the latter separation mode loses the high resolution characteristic for the FFF family due to high hydrodynamic dispersion interrelated to the shape of the cross section.

Limitations of Channel Configuration and Construction

Planar electrical FFF systems have been constructed, where the walls are defined by membranes permeable to the carrier liquid but not to the particles to be separated. In later versions these membranes are supported by porous or perforated plates. The membranes prevent the loss of the sample while allowing the passage of an electric current. Platinum wire electrodes lying outside the channel provide the transverse electric field. The carrier liquid represents a buffer, and a solution of identical composition is circulated through the chambers housing the electrodes in order to remove electrolysis products and reduce electrode polarization. Other configurations such as a hollow fibre systems and an annular porous glass channel have been reported. Presently, graphite or gold-plated glass channel walls are used, which minimize these effects. In a micro-machined channel for EIFFF, the electrode walls were of titanium and gold.

The resolution increases with the effective voltage drop across the channel, and increasing the applied voltage will have a positive effect on the resolution. Unfortunately, EIFFF is mainly carried out in aqueous solutions, and voltages above 1.7 V applied across the fluid-wall interface will cause significant electrolysis and bubble formation. Since the EIFFF system requires a stable flow velocity profile, bubbles cause serious flow disturbances, and electrolysis must be avoided. High flow velocities can limit the formation of bubbles and allow voltages above 1.7 V, but the available voltage is still small. Thus bubble formation in the electrochemical reactions at the wall electrodes is the limiting factor for the applied voltage.

Another voltage-related difficulty is the potential drop in the electric double layers near the channel walls. An electric double layer will cause most of the voltage drop to occur very close to the channel walls. As a consequence, the effective field which may be used for particle redistribution and separation, in the EIFFF system, is greatly reduced. Experimental data indicate that the effective field strength in the flow inside the channel is in the range of 0.25%–1% of the applied field depending on the composition of the buffer. Though this effect greatly reduces the performance of the EIFFF system, it is still able to perform separations. Due to the low electric field strength, Joule heating is not expected to be a significant problem in EIFFF, in contrast to electrophoresis systems.

One problem that arises in the separation in FFF systems is the symmetric parabolic velocity profile of the flow that performs the separation function. Indeed, particles with equal and opposite zeta-potential

will elute at the same time from the channel. This can be a problem for samples containing both positively and negatively charged particles. Though such particles are usually prone to coagulation or aggregation, these processes may be slowed by a steric stabilization, for example, as in polyelectrolyte solutions or particles with adsorbed polymers. The coagulation or aggregation kinetics may then be studied by EIFFF. Most samples, and especially biological samples, are of a uniform charge type. Biological samples contain mostly negatively charged particles (at least the particles of interest). For samples containing both types of particle charge, the asymmetrical flow velocity profile and an additional particle velocity asymmetry may be arranged by the application of a longitudinal electric field in a channel having walls with different zeta-potentials, which can cause electroosmotic flow with a non-uniform velocity profile.

The establishment of Boltzmann equilibrium distribution in the channel requires a relaxation time for a particle to migrate from one channel wall to the other in the applied electric field. If the drift velocity U is constant, the relaxation time will be found using eqn [1]:

$$\tau_r = \frac{w}{U} \quad [4]$$

In conventional EIFFF systems, the relaxation time typically is over 5 min, but in micro-machined EIFFF systems it may be less than 3 s.

EIFFF and Related Electrophoretic Methods

The nearest relatives of EIFFF are different electrophoresis techniques in liquids. However, electrophoresis systems often require very high field strengths for resolution, and the high voltages are limited by the Joule heating. Particle electrophoretic mobilities should also be high enough to have an acceptable resolution in common capillary lengths. Another type of electrophoresis separation system, free-flow electrophoresis, utilizes an electric field across a curtain of buffer between two vertical plates (a principle very close to FFF) and allows for continuous sample injection, but limits the detection and collection systems to the certain number of fractions. Resolution in free-flow electrophoresis is limited by fraction spreading in the fluid stream caused by the parabolic flow profile. Other methods of separating molecules and cells are needed for applications, where these limitations preclude the use of existing systems. Field flow fractionation is the solution for some applications, where particle electrophoretic mobilities are too low for the conventional

electrophoresis systems and high electric field strengths are not desirable. ElFFF has all the advantages of FFF systems, i.e., the ability to separate cells, large molecules, colloids, emulsions, and structure, which are too delicate for electrophoretic separation such as liposomes, both in the 'original' condition and after surface modification. Unlike the free-flow electrophoresis systems, elution in FFF systems is zonal and proceeds through one outlet port; for this reason, it is capable of significantly higher resolution. Therefore, anticipated applications of ElFFF systems include cell separations, characterization of emulsions, liposomes, and other particulate vehicles for intravenous drug administration with respect to size, charge, and stability, diagnostic tests for specific molecules in colloidal suspensions, quick and accurate separations of molecules, environmental water monitoring, tests for sample contamination, and further research involving zeta-potentials. ElFFF systems also find application as sample pretreatment systems by performing an initial separation on a sample, which is later collected for further testing by another analysis system.

The resolution of ElFFF is determined in the standard way for chromatography, i.e. by the comparison of the sum of the peak dispersions for two neighbouring peaks to the difference of their maxima. The resolution of ElFFF is inversely proportional to the separation distance of the electrodes; thus, the smaller the distance between the channel walls, the higher the resolution between two distinct particles, making ElFFF an ideal application for using micro-machining techniques. The resolution increases with the square root of the channel length, so the longer the channel the better the resolution, but the time required for the improved resolution increases, which is not generally desirable.

Combined Electric-Thermal FFF (El-ThFFF)

An interesting combined technique represents the application of an electric field across the channel for Thermal FFF, where a temperature gradient is used to separate the analysed particles. After a potential drop of about 2 V is applied, the ThFFF retention is apparently changed. This combination allows a more exact examination of the particle surface properties, since ThFFF, like electrophoresis, represents a surface kinetic phenomenon defined by the surface force potential. Also, this combined FFF method gives information on particle electrokinetic properties in non-aqueous solution. El-ThFFF may allow distinction between electrostatic and non-electrostatic interactions in surface layer by

programming of the electric field strength during the separation.

Conclusion

ElFFF is a method for the separation of charged particles and macromolecules according to their effective charge. This parameter is not measured by electrophoretic methods and may be obtained directly from ElFFF experiments. The effective charge may be used for the characterization of surface particle properties and macromolecule charged groups, when the required theory has been developed. ElFFF has electric field strength limitations due to electrochemical reactions at the channel walls and potential interface drop.

Field Flow Fractionation: Thermal

Introduction

Field flow fractionation (FFF) represents a class of separation techniques, which are one-phase methods. They are preferable for the separation and characterization of mixtures such as high molecular weight polymers which might be modified or damaged in two-phase separation methods like chromatography. FFF uses a force field perpendicular to the direction of separation to control the longitudinal velocity of particles injected into the system. It is achieved by the particle redistribution in a flow with a parabolic velocity profile due to the transverse force action. In Thermal FFF (ThFFF), the transverse movement of the particles is caused by the particle 'thermophoresis' in the temperature gradient. The transverse particle velocity, U , is defined by the expression:

$$U = b_T \cdot \nabla T \quad [1]$$

where b_T is the particle thermophoretic velocity, and ∇T is the transversal gradient of the temperature in the channel. The particle thermophoresis is commonly related to the osmotic pressure gradient produced in the surface layer due to the temperature gradient. This excess osmotic pressure is established in the particle surface layer due to accumulation of the solvent or dissolved molecules or ions in the particle surface layer. This accumulation is related to the particle surface potential Φ . This surface potential may have the electrostatic nature, when the particle surface carries electric charge, or represent some kind of dipole-dipole interaction, when ion adsorption or surface group dissociation is impossible. The latter situation should be characteristic for organic solvents, where dispersion interaction between the particle surface and solvent molecules should play the main role. The theory of thermophoresis is developed mainly for particles larger in size than the characteristic thickness of the surface layer and having moderate surface potential of several kT (k is the Boltzmann constant), which interacts with dissolved ions or molecules. These ions or molecules should be present at a concentration low enough to avoid the excluded volume effects in their accumulation in the particle surface layer. In this situation, the particle ther-

mophoretic mobility may be written as

$$b_T = \frac{3kc_0}{\eta(2+n)} \int_0^\infty y dy \left(1 + n \frac{y}{R}\right) \left[e^{-(\Phi/kT)} \left(\frac{\Phi}{kT} + 1\right) - 1 \right] \quad [2]$$

where c_0 is the solute concentration in the carrier liquid, η is the carrier liquid viscosity, R is the particle diameter, n is the particle-to-liquid thermal conductivity ratio, and y is the transverse coordinate in the surface layer. The immediate physical factor for the particle thermophoresis is the 'slip' liquid flow in the particle surface layer due to the osmotic pressure gradient, which is related to the temperature gradient in the particle surface layer established along the macroscopic temperature gradient in the liquid. Thus, the main physical events in thermophoresis take place near the particle surface, though the temperature gradient near the particle surface playing the role of the driving force for the particle is defined by the particle and liquid thermal conductivity, which are bulk properties. However, one can expect that these bulk properties will be the same for small particles and larger samples of the material, and the particle thermal conductivity can be obtained from literature data on thermal conductivity of the material or independent experimental determination. It means that particle thermophoresis is mainly related to particle surface properties. It becomes absolutely true for metal particles with very high thermal conductivity, when the parameter n in eqn [1] is very large. For metal particles, the particle thermophoretic mobility is a function of the particle surface properties only. For smaller particles with higher surface potentials, eqn [1] is not true due to intensive solute transport in the particle surface layer.

This surface transport should be compensated by the solute diffusion outside the surface layer, and which, in turn, leads to the solute concentration gradient and related electric field establishment (in electrolytes) around the particle (so-called concentration polarization). However, for a particle with moderate size and thermal conductivity having a surface potential about two to four kT , we can state that the particle thermophoretic mobility is defined by the particle surface properties and does not depend on its size. For emulsion droplets, the thermophoretic mobility in the absence of concentration polarization

is determined as:

$$b_T = -\frac{3k\epsilon_0 R \cdot \nabla T}{(2\eta + 3\eta_i)(2 + n)} \int_{-\infty}^{\infty} \left(1 + n \frac{y}{R}\right) \times \left[e^{-(\epsilon/kT) \left(\frac{\phi}{kT} + 1\right)} - 1 \right] y dy \quad [3]$$

where η_i is the viscosity of the liquid inside the droplet. For homopolymer chains, it is shown by ThFFF experiments, that chain thermophoretic mobility does not depend on chain length and branching, and one can expect that eqn [2] will define it accurately, where R will be the monomer radius. The theory of particle thermophoresis may be true, if some solutes present at low concentration, for example, salt ions, are accumulated around the monomers. However, in true polymer solutions, where no dissolved extrinsic solutes are present, excluded volume effects cannot be neglected, and eqns [2] and [3] cannot be used for the description of thermophoretic behaviour.

For calculation, the Boltzmann exponent indexes in eqns [2] and [3] may be simplified using the approximation:

$$\frac{\Phi}{kT} \approx -\epsilon \left(1 - \frac{x}{h}\right) \quad [4]$$

where ϵ is the depth of the surface potential well in kT units, and h is the characteristic width of this well. Typical orders of values for different kinds of surface potentials are present in Table 1, where A is the Hamaker constant, d is the solute radius, q is the solute electric charge, ζ is the particle zeta-potential, and λ is the Debye length.

For the characteristic relaxation time, the Boltzmann transverse particle distribution is established in the system by forcing injected particles toward the wall of the channel and by their diffusion motion. In ThFFF, particles of the same size with higher ther-

mophoretic mobility will be accumulated more closely to the wall, while particles of lower thermophoretic mobility will form a more diffuse layer that extends further into the flow of the carrier liquid. For particles with about the same thermophoretic mobility, the thickness of this layer may also be different, if particles have different diffusion coefficients, D . Particles with higher diffusion coefficient (i.e., with smaller size) will be accumulated in a more extensive layer due to more intensive thermal movement. The thermophoretic mobility related to the surface potential is an important parameter interrelated to the particle surface charge density (where it represents the electrostatic potential) and characterizing the particle surface properties and the possible exchange of substances between the particle and the surrounding liquid. Also, the separation of particles of the same material but with different sizes may be important in the characterization (molecular mass distribution) of commercial latex and polymer particles.

ThFFF is carried out in a thin channel of rectangular cross-section with a width to thickness ratio (aspect ratio) of about 100 (thickness about 10–100 microns). It allows the separation system to approximate to the laminar flow between infinite parallel plates, which is characterized by a parabolic velocity profile, where the fluid velocity at the channel walls is zero, and a maximum in the centre of the channel. Thus, if a group of particles are accumulated, maintaining an average distance from the wall different from another group of particles, their velocities along the channel will be different. As a consequence, they will leave the channel at distinct times, related to the particle thermophoretic mobility and size, which defines the particle diffusion coefficient. There are no other direct methods, where temperature gradients are used for particle, droplet or macromolecule separation. FFF systems are elution methods and allow the collection of fractions during a separation.

Table 1

Surface potential	Analytical expressions for the $\Phi(y)$, ϵ and h			The ranges of values for parameters ϵ and h	
	$\Phi(y)$	ϵ	h	ϵ	h
Van der Waals forces	$-A(d/r)^6$	A/kT	$d/3$	5–50*	10^{-8} cm (low-molecular surfactant)
Coulomb electrostatic forces	$-q\zeta'' e^{-(y/\lambda)}$	$q\zeta''/kT$	λ	0–10	10^{-7} – 10^{-4} cm** (aqueous electrolytes)
Adsorption forces	None	None	None	0–10	$\approx 10^{-7}$ cm
Structure forces	None	None	None	0–10	$\approx 10^{-5}$ cm

*The maximum values of Hamaker constant are reached for metals

**The maximum value of the Debye length is calculated for the deionized water.

Channel Configuration and Construction Limitations

In thermal FFF the temperature gradient across the channel thickness is maintained by the electrical heating of a polished metal block (usually a chrome or nickel-plated copper block) forming one wall and a cooled similar block forming the opposite wall. The plating improves resistance to corrosion, the factor limiting the range of permitted solvents and the separated particles and macromolecules. Cooling is usually accomplished by passing cold water through longitudinal holes bored in the block. To prevent thermogravitational convection, it is the upper block that is heated and the bottom one cooled. Thermocouples are mounted in the blocks to control their temperatures. In the bottom block, capillaries for the introduction and elution of the solvent and the sample are placed. The copper blocks are separated by a spacer of a polymer material with a low thermal conductivity (Mylar, Kevlar, etc.) to provide high temperature gradients. The channel constructions are described more exactly in the literature (see Further Reading). One of the main advantages of the FFF family stems from the uniform open channel geometry and the well-defined flow profile. As a consequence, retention can be related directly to the physicochemical parameters of the analyte material and carrier liquid. Possible deviations of the flow profile and the polymer parameters due to the non-uniform temperature distribution have been described.

Polymer Characterization

Progress in ThFFF instrumentation and methodology has allowed a systematic study on the thermal diffusion of polymer solutions. The success of these studies is provided by the ability of ThFFF to produce accurate values of thermal diffusion parameters using small quantities of polymer (a few hundred micrograms). The values of the thermal diffusion coefficients (parameters equal to the thermophoretic mobility) have been obtained for 17 polymer-solvent systems and are about 10^{-8} – 10^{-7} $\text{cm}^2/\text{s} \cdot \text{K}$, and their molecular masses are from about several tens to about hundred Daltons. The results show the correlation of the polymer thermophoretic mobility with several polymer and solvent parameters, the thermal conductivity of the polymer and solvent, the polymer density, and the viscosity and viscous activation energy of the carrier liquid. Studies also demonstrated a correlation of the polymer thermophoresis parameters with the solvation properties of the solvent. Though conventional diffusion in polymer solutions is well defined, the thermal diffusion of poly-

mers in liquids is not exactly understood and not well characterized. Although there are equations relating retention to experimental parameters and transport coefficients of polymers, values of polymer thermophoretic mobility are not commonly available, and a model for predicting them from physicochemical parameters is in progress only. Therefore, a calibration is necessary for characterizing the molecular weight distribution (MWD) of polymers by ThFFF (although a single calibration point can be used, when the dependence of the diffusion coefficient on molecular weight is known). Calibration is simple in the analysis of homopolymers because well-characterized molecular weight standards are available for a variety of polymers.

The characterization of copolymers presents more problems because of the overlapping effects of composition and molecular weight distribution (MWD). Often it is necessary to characterize both the MWD and the compositional distribution. In this case the commonly used method of size exclusion chromatography (SEC) is not adequate because the separation is governed by size alone. Thus, molecular weight fractions with different compositions may be eluted in SEC simultaneously. In contrast, ThFFF may separate polymers by both chemical composition and size, and is therefore capable of yielding both size and compositional information on copolymers. Separation by size in ThFFF is governed by differences in the diffusion coefficient of the polymers, while separation by chemical composition may result from differences in the thermophoretic mobility.

The results on ThFFF of random and block copolymers of polystyrene (PS) and polyisoprene (PI) in tetrahydrofuran and cyclohexane show that for random copolymers and block copolymers with a random configuration in solution, the thermophoretic mobility is a linear function of monomer composition. It may be a basis for obtaining compositional information on such copolymers by ThFFF. For copolymers with a radial segregation of monomers, thermophoresis is determined mainly by monomers located in the outer region of the polymer coil. The dependence of retention on the radial distribution of monomers provides a basis for evaluating bonding arrangements in copolymers. The further progress in copolymer characterization by ThFFF is related to progress in the theory of the polymer thermophoresis.

Particle Characterization

Though most ThFFF samples are polymers, the ability of ThFFF to retain and separate both submicron and micron size particles (latex and silica) suspended in various organic carrier liquids has also been

demonstrated by Shiundu, Lee and Giddings. In their article, the dependence of particle retention on various factors (solvent properties, amount of added electrolyte, particle size and composition, and cold-wall temperature) is evaluated and discussed.

Thermophoretic mobilities of several latex-solvent combinations have been obtained from the ThFFF retention data. The studies were carried out in polar organic solvents, cyclohexane and aqueous carriers. As a rule, the thermophoretic mobilities of particles range from 10^{-8} to 10^{-7} $\text{cm}^2/\text{s}\cdot\text{K}$, while the particle size ranges from about 0.04 to about 1 micron.

The retention of colloidal particles in ThFFF demonstrates a strong dependence on the chemical composition of the particles or their surfaces. These results are observed among both similar particles (such as latex particles) and different particles (including latex particles, and inorganic and metallic colloids). These compositional effects are observed for particles suspended in both aqueous and non-aqueous carrier liquids. Also, metal particles (e.g. palladium) are less retained than silica particles, with latex particles most retained. The resolution of particles of equal size in ThFFF experiments is also demonstrated. Surface compositional effects were also demonstrated in this study. These effects confirm the possibility of colloid particle surface analysis by thermal FFF.

Combined Electric-Thermal FFF (EI-ThFFF)

An interesting combined technique represents the application of an electric field across the channel for Thermal FFF, where a temperature gradient is also established. For details see Particle Size Separation/Field Flow Fractionation: Electric Fields.

Conclusion

ThFFF is a method for the particle and macromolecule separation in electrolyte and non-electrolyte solvents according to their interaction with the solvent molecules or/and ions of the added salt. For particles, these are surface interactions, though the particle/solvent thermal conductivity ratio is also important. Thermophoretic mobility may be cal-

culated immediately from ThFFF experimental data, when the particle or macromolecule diffusion coefficient is known. This parameter may depend on both electrostatic and non-electrostatic (dispersion) interactions and can be used for their characterization. Also, the thermophoretic mobility may be used for the characterization of surface particle and macromolecule properties, when the respective theory is developed.

Hydrocyclones for Particle Size Separation

J. J. Cilliers, UMIST, Manchester, UK

Copyright © 2000 Academic Press

Introduction

The hydrocyclone is a static, continuous particle size separation device that can also be used for phase separations, including solid–liquid, liquid–liquid and liquid–gas separations and has been used for various classification duties since the 19th century.

Hydrocyclones are attractive for industrial use as they have no moving parts, a small footprint, relatively low capital and operating costs, and are simple to operate. On the other hand, their operation is rather inflexible once installed and single-stage efficiencies may be low, especially for particles finer than 10 μm .

This article describes the mode of operation of hydrocyclones, and the motion of fluid and solid particles in the classifier. Quantifying the separation is followed by the effect of the major design and operating variables on the efficiency.

Two modelling approaches are introduced: a fundamentally based model, including computational fluid dynamics (CFD), and empirical models, which are still in general use.

The article concludes with aspects of further development.

Description

Hydrocyclones are cono-cylindrical in shape, with a tangential feed inlet into the cylindrical section and an outlet at each axis. The outlet at the cylindrical section is called the vortex finder and extends into the cyclone to reduce short-circuit flow directly from the inlet. At the conical end is the second outlet, the spigot. For size separation, both outlets are generally open to the atmosphere. Hydrocyclones are generally operated vertically with the spigot at the lower end, hence the coarse product is called the underflow and the fine product, leaving the vortex finder, the overflow. **Figure 1** schematically shows the principal flow and design features of a typical hydrocyclone: the two vortices, the tangential feed inlet and the axial outlets. Except for the immediate region of the tangential inlet, the fluid motion within the cyclone has radial symmetry. If one or both of the outlets are open to the atmosphere, a low pressure zone causes a gas core along the vertical axis, inside the inner vortex.

The operating principle is simple: the fluid, carrying the suspended particles, enters the cyclone tangentially, spirals downward and produces a centrifugal field in free vortex flow. Larger particles move through the fluid to the outside of the cyclone in a spiral motion, and exit through the spigot with a fraction of the liquid. Due to the limiting area of the spigot, an inner vortex, rotating in the same direction as the outer vortex but flowing upward, is established and leaves the cyclone through the vortex finder, carrying most of the liquid and finer particles with it. If the spigot capacity is exceeded, the air core is closed off and the spigot discharge changes from an umbrella-shaped spray to a ‘rope’ and a loss of coarse material to the overflow.

The diameter of the cylindrical section is the major variable affecting the size of particle that can be separated, although the outlet diameters can be changed independently to alter the separation achieved. While early workers experimented with cyclones as small as 5 mm diameter, commercial hydrocyclone diameters currently range from 10 mm to 2.5 m, with separating sizes for particles of density 2700 kg m^{-3} of 1.5–300 μm , decreasing with increased particle density. Operating pressure drop ranges from 10 bar for small diameters to 0.5 bar for

Figure 1 Principal features of the hydrocyclone.

large units. To increase capacity, multiple small hydrocyclones may be manifolded from a single feed line.

Although the principle of operation is simple, many aspects of their operation are still poorly understood, and hydrocyclone selection and prediction for industrial operation are largely empirical.

Liquid Velocity Distributions

Kelsall, in 1952, performed a classic series of experiments measuring axial and tangential fluid velocity profiles in a hydrocyclone using an ingenious experimental system with rotating objectives. The radial velocity was calculated by continuity. The velocity profiles are shown in **Figure 2**. More recently, velocity profiles measured using laser Doppler velocimetry (LDV) were found to correspond closely to those of Kelsall.

The fluid velocity in the cyclone has tangential, axial and radial components. The axial velocity is negative (downward) close to the walls in the cone and positive (upward) near the air core, increasing towards the spigot. This results in a locus of zero vertical velocity between the two vortices, which roughly follows the profile of the cyclone. Toroidal rotation in the inlet flow and interaction between the vortices result in multiple flow reversals.

The tangential velocity increases toward the axis, reaching a maximum near the air core, thereafter decreasing in a forced vortex region. It is the tangential velocity component that generates the centrifugal force, which separates coarser particles from finer ones. The radial velocity, which is two orders of magnitude smaller than the axial or tangential velocities, is directed toward the centre of the cyclone and increases toward the apex.

Particle Motion

Particles entering the cyclone move radially, depending on their mass, either outward due to tangential liquid motion, or inward due to radial fluid motion. In the radial and axial directions, the particle motion is assumed to equal the fluid motion.

Direct measurement of particle motion and solids concentrations at positions in the hydrocyclone can be performed using phase Doppler anemometry. Electrical impedance tomography has been used to measure the position of the air core and the solids concentration profile in a plane through industrial hydrocyclones.

Classification Performance and the Partition Curve

The partition curve (also called a performance curve, efficiency curve or Tromp curve) is used to quantify

hydrocyclone particle size separation performance. It quantifies the weight fraction (or percentage) of each particle size fraction in the feed reporting to the underflow product. For any particle size d , the partition number, $p(d)$, is calculated from:

$$p(d) = \frac{U \cdot u(d)}{F \cdot f(d)} \quad [1]$$

U and F are the mass flow rates of solids (in the same units) and $u(d)$ and $f(d)$ are the weight fractions of particle size d in the feed and underflow streams, respectively. The size at which the partition number equals 0.5 (or 50%) is called the cut size (d_{50}).

A fraction of fine particles always report to the underflow, hence experimentally observed partition curves do not asymptote to zero but to a minimum, called the bypass. This can be interpreted as a fraction of all particles in the feed bypassing classification and reporting directly to the underflow stream. Short-circuiting of feed material to the overflow stream may cause the partition curve not to reach a partition value of 1 (100%); this is not common. The effect of bypass on classification performance is taken into account by correcting the partition value:

$$c(d) = \frac{p(d) - r(d)}{1 - r(d)} \quad [2]$$

where $c(d)$ is the corrected partition value and $r(d)$ the fraction of material of size d bypassing classification. The particle size at which the corrected partition number is 0.5 (50%) is called the corrected cut size (d_{50c}). It is often found that the bypass equals the water recovery from the feed to the underflow (R_F), although there is no fundamental reason why this should be so.

Figure 3 schematically shows an observed and corrected partition curve.

A so-called fishhook may occur in the observed partition curve when, for particle sizes finer than that at the minimum partition value, progressively higher partition numbers are observed. This is more commonly observed for smaller diameter hydrocyclones and is thought to be the result of turbulent dispersion. In such cases the water recovery may be significantly lower than the lowest partition value observed. Applying the correcting concept to such partition curves is meaningless.

Mathematically Describing the Partition Curve

Corrected partition curves have a sigmoidal shape that can be represented using two-parameter

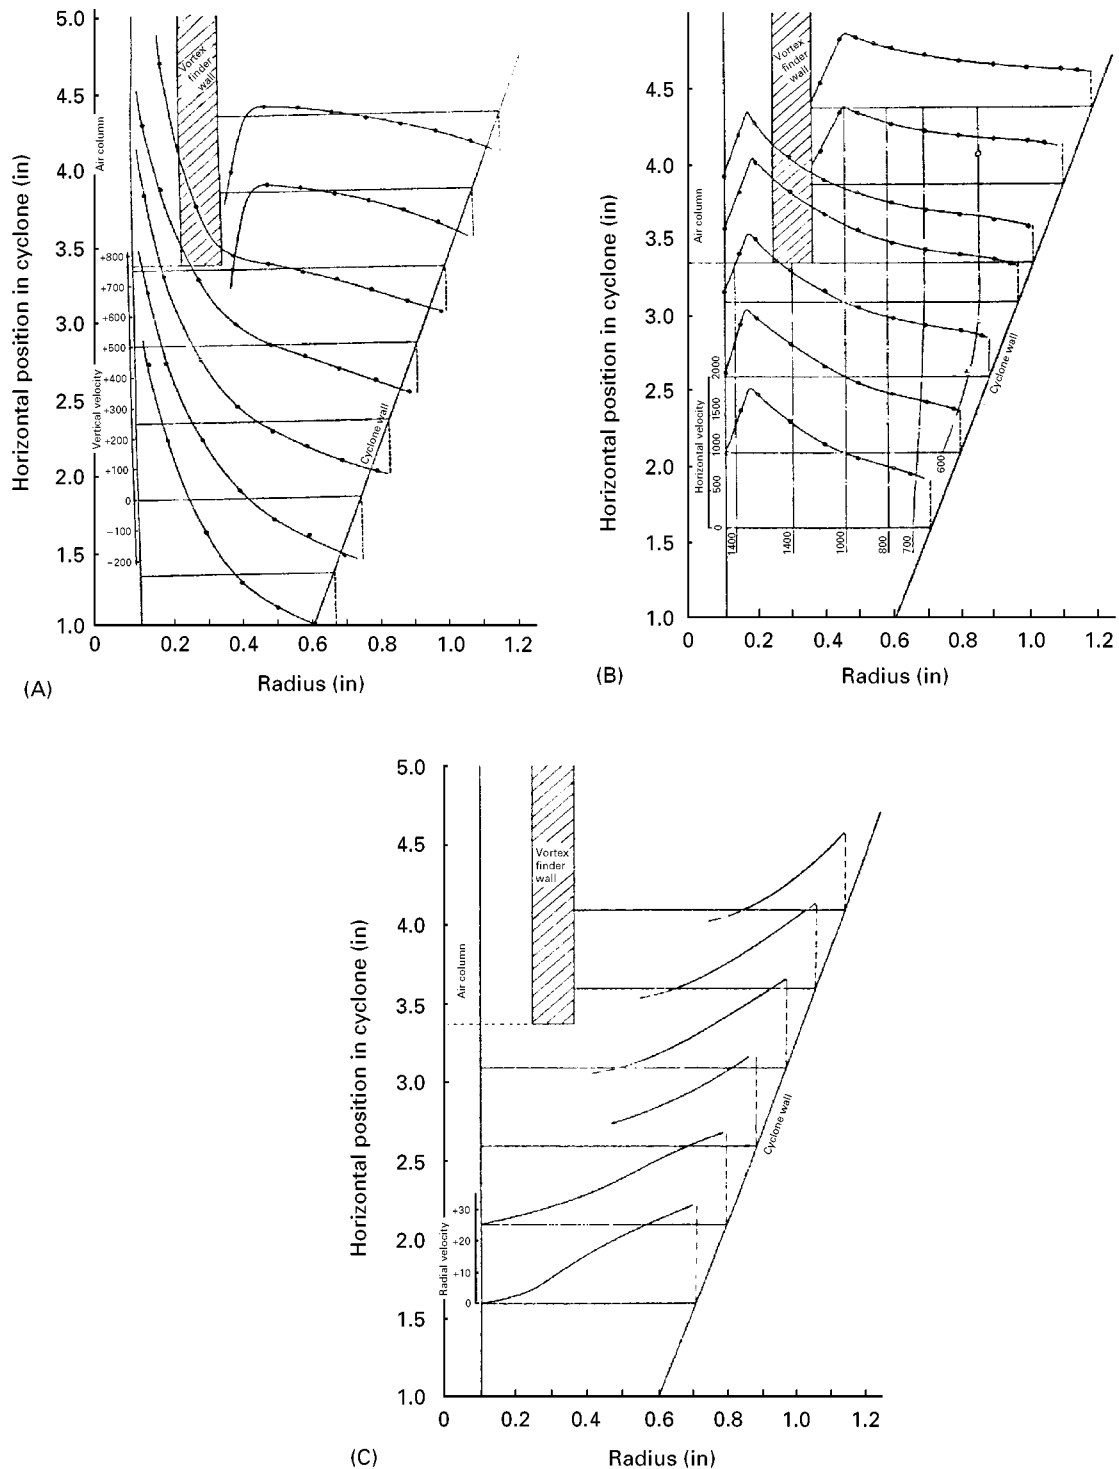

Figure 2 (A) Axial, (B) tangential and (C) radial velocity profiles in a hydrocyclone. (Reproduced with permission from Kelsall (1953).)

functions such as the exponential sum, the Rosin-Rammler and the log-logistic expressions. The two parameters determine the cut size and the sharpness of separation, respectively. The fishhook partition curve can be modelled using the sum of a corrected

partition curve and an inverted partition curve multiplied by a bypass fraction.

The observed partition curve gives a complete description of the selective separation of all sizes of solids entering a cyclone and can be used to predict

Figure 3 The observed (continuous line) and corrected (dashed line) partition curves of a hydrocyclone with a bypass of 20%.

the product size distribution and solids recovery for changes in feed size distribution. If the bypass is assumed to equal the water recovery, the liquid and volumetric balances can also be estimated.

Hydrocyclone Geometry

The hydrocyclone diameter is the main design variable, and affects both capacity and cut size. The broad operating range available for any hydrocyclone diameter is narrowed down by fixing the inlet and outlet dimensions. It is not generally possible to select independently all the design variables; however, there are reasonable ranges in relation to the hydrocyclone diameter, D_c . **Figure 4** shows the approximate cut size and throughput range that can be achieved using cyclones of different diameters.

The cone angle for classification of hydrocyclones is $15\text{--}30^\circ$, with smaller angles for finer cut sizes, and larger angles for coarser cut sizes, respectively. The free vortex height is the distance between the bottom of the vortex finder and the spigot. Increasing hydrocyclone height improves both capacity and separation efficiency, and generally varies between 3 and $8 D_c$.

The inlet opening is usually rectangular with a height to width ratio of 2 and an equivalent circular diameter of $0.14\text{--}0.33 D_c$. The inner wall, outer wall or centre of the hydrocyclone inlet may be designed to be tangential to the cyclone body, and may also scroll downwards.

The outlet dimensions are the most important physical parameters used to alter the operation. Vortex finder diameters of $0.13\text{--}0.43 D_c$ are commonly used. Spigot diameters in the range $0.1\text{--}0.2 D_c$ are used, but the ratio to the vortex finder is more important. In general, the vortex finder diameter is greater than that of the spigot. Equal diameters should be avoided.

The Effect of Operating and Design Variables

Table 1 summarizes the effect that changes to the major design and operating variables have on the capacity, cut size and sharpness of classification.

The effect of pressure drop on the sharpness of separation depends on the operating range, as an increase in pressure drop increases the throughput and hence the separation efficiency, but decreases the volumetric flow to the underflow. Of particular interest is the effect of feed solids concentration, which has a significant effect on the classification. **Figure 5** shows clearly that an increase in solids concentration increases the cut size and reduces the sharpness of separation.

Hydrocyclone Models

The modelling of hydrocyclones is performed by either describing the fluid flow and particle motion within the cyclone, or by developing empirical

Figure 4 Cut size and throughput for different cyclone diameters.

(or semi-empirical) relationships between operating variables and measured responses. Fundamental models are appealing from a rigorous standpoint but have difficulty in describing satisfactorily the complex particle–particle and particle–fluid interactions for hydrocyclones operating at higher solids concentrations.

Empirical or semi-empirical models, which relate the parameters of the partition curve to cyclone design and operating variables, are generally used for industrial hydrocyclone modelling and simulation. A number of general models, particularly for larger diameter hydrocyclones, have been developed (see Further Reading).

Fundamentally Based Hydrocyclone Models

Early attempts at understanding the physical principles that govern size separation in hydrocyclones yielded theories based on equilibrium, residence time and crowding. More complete simulations in which

fluid and particle motion is estimated from solution of the Navier–Stokes equations have been developed more recently.

Equilibrium orbit theory It can be postulated that particles will find an equilibrium orbit in the hydrocyclone where their terminal settling velocity radially outward is equal to the radial velocity of the liquid inward. A particle will report to the spigot if its equilibrium orbit is in the downward axial liquid flow and to the vortex finder if in the upward axial flow. The cut size is defined by particles that have an equilibrium orbit that coincides with the locus of zero vertical velocity and therefore have an equal probability of reporting to either product streams. An equilibrium orbit may not be achieved due to the short residence times and high solids concentrations in the hydrocyclone.

Residence time theory This theory determines whether the residence time in the hydrocyclone allows a particle entering the cyclone at the centre of the inlet to settle to the cyclone wall and enter the boundary layer flow to the underflow.

Crowding theory At higher feed concentrations, it is found that the separation size is primarily determined by the discharge capacity of the spigot and the feed size distribution. By controlling the outlet dimensions, it is thought that any cut size within the feed size distribution can be obtained.

Computational fluid dynamics (CFD) solutions This is the preferred approach for fundamentally based modelling of hydrocyclone performance. Complete flow modelling of the hydrocyclone

Figure 5 Effect of feed solids concentration on hydrocyclone separation. Circles, 2.68 vol%; squares, 11.11 vol%; triangles, 17.54 vol%; diamonds, 23.75 vol%. (Reproduced with permission from Braun and Bohnet (1989). Copyright: Wiley-VCH.)

involves predicting the liquid-phase velocities, the slurry concentration profile, the turbulent viscosities and the slip velocities of particles with respect to the liquid phase for a range of particle sizes before predicting the partition curve. The solution is complex, because the governing fluid flow equations are nonlinear, simultaneous partial differential equations.

Chakraborti and Miller (1992) have published an extensive review of fluid flow modelling in hydrocyclones. They describe the flow models in detail, giving particular attention to models based on the Navier–Stokes equation and the treatment of fluid turbulence. They further discuss techniques for flow measurement and visualization and give a brief summary of pressure drop correlations and measurements. This paper is an essential reference for the fluid flow modelling approach.

The general approach to develop a complete CFD-based model of a hydrocyclone must include a wide range of components. If it is assumed that variations of local density and viscosity are small for dilute slurries and that particle–particle interactions are negligible, the fluid and particle modelling can be decoupled. Liquid velocities are predicted by combining the fluid transport equations for vorticity, stream function and angular spin velocity with a modified Prandtl mixing length model, which varies both radially and axially, for the turbulent viscosity. The set of simultaneous, nonlinear partial differential equations are solved by overlaying the hydrocyclone dimensions with a rectangular grid and using appropriate boundary conditions at the solid walls and liquid–air interface, to solve for conditions within each cell of the grid. By balancing all the forces on the particle, the particle motion with respect to the fluid can be computed. The particle trajectories are found by calculating axial and radial slip velocities with respect to the fluid. Size classification performance is determined by following a particle of a given size from the inlet until it exits. This computation is repeated for each particle size across the inlet diameter yielding the partition curve.

For concentrated slurries, liquid-phase velocities are affected by local density and viscosity, which in turn are affected by local solid concentration and particle size distribution. Since particle motion determines the concentration and size distribution at each location, this being determined from liquid velocities, an iterative solution is required so that local slurry property changes can be estimated and liquid-phase velocities recalculated.

Advances in CFD methods such as computation grid generation, numerical methods and computing

resources are increasing the applicability of this modelling technique to improve designs.

Empirical Models

At present, empirical models are the most commonly used technique for hydrocyclone selection and performance prediction. Empirical hydrocyclone models use the partition curve as a basis for describing size separation. Suitable equations are developed from experimental results to relate the parameters of the corrected partition curve to physical variables. In general, empirical hydrocyclone models consist of four relationships that describe the cut size, the sharpness of separation, the water balance around the hydrocyclone and the throughput–pressure drop relationship.

An empirical hydrocyclone model was described in 1976 that is still commonly used to predict separation performance. This model was the first to document an empirical form for the sharpness of separation and therefore allow direct simulation of expected performance without any testwork. This model form is often used as a basis for the development of models that include further variables, such as, for example, angle of inclination, or for an operating range in which the model has not been tested.

The Rosin–Rammler function describes the reduced partition curve:

$$c_i = 1 - \exp(-0.693x_i^m) \quad [3]$$

where m indicates the sharpness of separation and x_i is:

$$x_i = \frac{d_i}{d_{50c}} \quad [4]$$

In SI units, and using the symbols in Table 1, the Plitt equation for the cut size is:

$$d_{50c} = \frac{50.5 D_c^{0.46} D_i^{0.6} D_o^{1.21} \exp[6.3\phi]}{D_u^{0.71} b^{0.38} Q^{0.45} (\rho_s - \rho_l)^{0.5}} \quad [5]$$

where ρ_s , ρ_l and ρ_p are the densities of the solid, liquid and pulp, respectively.

To describe the water balance, Plitt develops a relationship for the volumetric flow split between the overflow and underflow streams, S , rather than the bypass:

$$S = \frac{3.28(D_u/D_o)^{3.31} b^{0.54} (D_u^2 + D_o^2)^{0.36} \rho_p^{0.24} \exp[0.54\phi]}{p^{0.24} D_c^{1.11}} \quad [6]$$

The relationship for the sharpness of separation is given by:

$$m = 1.94 \exp[-1.58 R_v] \left[\frac{D_c^2 b}{Q} \right]^{0.15} \quad [7]$$

where R_v , the recovery of slurry to the underflow, is related to the flow split by:

$$R_v = \frac{S}{1 + S} \quad [8]$$

The relationship between the pressure drop across the cyclone and the throughput is given by:

$$P = \frac{1.88 Q^{1.78} \exp[0.55 \phi]}{D_c^{0.37} D_i^{0.94} b^{0.28} (D_u^2 + D_o^2)^{0.87}} \quad [9]$$

Roping is affected by the spigot diameter and the volumetric solids concentration in the underflow; however, there is no satisfactory method for predicting operating limit.

It must be emphasized that empirical models, although developed from an extensive database, should be used with caution.

Future Developments

The extremely wide range of hydrocyclones available and separation applications for which they can be used assures their future role in particle classification. However, significant obstacles remain before they can be used to replace more efficient methods for fine classification purposes, such as centrifuges. Classification inefficiencies, in particular the large bypass, limit their application. The potential of very small diameter hydrocyclones for sub-micron particle separation, especially in multistage configuration, is enormous, if these inefficiencies can be reduced.

Hydrocyclone modelling has advanced significantly with the use of CFD. Empirical hydrocyclone models are convenient ways of describing experimental data but do not enhance the understanding of the separation and CFD models will play a greater role in hydrocyclone simulation. Nonintrusive measurement techniques such as laser Doppler anemometry (LDA), laser Doppler velocimetry (LDV) and tomography have indicated the source of hydrocyclone inefficiencies. With increased resolution and combined with CFD models, this will improve hydrocyclone unit design.

Hydrocyclone operations will benefit from novel methods for monitoring which are currently being developed. Industrial tomography is becoming affordable, and the potential of visual and sonic techniques has been illustrated.

Introduction

Sieving is one of the oldest and most commonly used method of sorting materials. Yet, when improperly carried out, sieving can provide misleading information or biased separation. Sieving has widespread application to industries as diverse as mining, pharmaceutical production and agriculture. The goal is typically to control or measure the particle size distribution. Sieving may be a direct part of a production process, a quality control procedure or a sample characterization. Regardless of the purpose, an understanding of sieving is necessary to optimize and accurately use this technique.

Sieving has the clear advantage of being a simple, readily understood and relatively inexpensive method. This method also has the ability to provide reproducible results. This has tended to boost confidence in the method, even where it is not warranted. Some of this confidence is a result of ignorance as to the actual errors involved in a given sieving operation or with a particular set of sieves. While these errors can be described and measured, the difficulty of doing so largely detracts from the attractiveness of the method. Thus, most people rely on standard procedures and the reproducibility of the method to reassure themselves as to the quality of the data obtained.

Overview of Sieving Process

Sieving was the earliest means of particle size fractionation. Basically, the process of sieving is that of placing the particles to be fractionated on a pattern of openings or holes. The individual openings are referred to as the aperture. Small particles may fall through or the sieve retains the larger particles. Separation requires agitation and time. A variety of mechanisms exist to provide agitation either to the sieve or to the particles to be fractionated. Typically, commercial equipment varies in the manner in which agitation is created or the fluid used to support the particles. Either air or water may be used to support the particles as they sort on the sieve. Dry sieving has a lower practical limit of 50 μm , while wet sieving can separate smaller particle sizes when using special sieves or small volumes of particles.

We briefly examine three applications of sieving processes before continuing in more detail with a description of the sieving process, the time dependence of sieving and lastly sources of error in sieving.

Applications of Sieving

A single sieve may provide a straightforward classification (or gradation) of particles where a clear threshold is desired. Crushing operations typically seek to ensure that all particles are below such a threshold and sieves provide a convenient means of doing so. However, in some operations it is equally important to remove particles less than a given size. The first case is referred to as scalping (removing oversize particles) while the second case is referred to as removal of fines. Sometimes it is desirable to do both. Thus, it can be useful to employ a set (or nest) of sieves varying in aperture size. Unsorted particles are applied to the topmost sieve and agitation begun. As the particles sort, smaller ones pass through from upper sieves to lower ones. This cascade of particle sorting continues as the smallest particles only gradually make their way past the smallest sieve.

A nest of sieves with a sufficient variation in aperture sizes may be used to construct a particle size distribution. Such distribution may in turn be used to describe the behaviour of the material under study. A particle size distribution obtained in this way should recognize that the errors associated with the top sieve (the coarsest fraction) may be different from the errors associated with the bottom sieve (the finest fraction). This occurs in part due to differing opportunity times for the particles to pass through the sieve that they are ultimately retained upon.

A third application of sieving is the use of sieving curves to develop a morphological characterization of the material being screened. Sieving curves represent the time dependence of the sieving process and are discussed in more detail in a later section. The goal is to infer particle shape or other morphological features (e.g. agglomeration) from the speed with which sieving proceeds. Unfortunately, these techniques are still in the developmental stages.

Description of the Sieving Process

Sieve Construction

Sieves are typically constructed in one of two ways: first, through the use of a wire mesh or cloth. This

Table 1 Sieve mesh equivalent sizes: US standard testing sieves designated for wire cloth at some principal ISO sizes

Mesh number: US standard testing sieves	Sieve opening (mm)
5	4.00
7	2.80
10	2.00
14	1.40
18	1.00
25	0.710
36	0.500
45	0.355
60	0.250
80	0.180
120	0.125
190	0.090
325	0.045

results in square apertures. The diameter of the wire controls the size of the aperture and per cent of the total area that is open. Second, openings or circular holes are created by perforating a plate or flat disc. The number of perforations controls the amount of open area in this sieve. These two methods result in openings that differ in shape and in their ability to pass particles. Thus, it is important to specify which kind has been used to obtain a particular set of data.

Sieves are available in standard sizes (Table 1) from a number of companies. Sieve openings are given in a mesh number or nominal diameter of the opening. Surprisingly, no standard sieve is readily available for the 50 μm cut-off between the sand and silt separates (as defined in some systems of particle nomenclature). Consequently, sieving cannot distinguish this class boundary directly using standard sieves. However, such boundaries (or other specific sizes) can be estimated by determining the particle size distribution with a nest of sieves that bracket the desired size.

Industry standards have focused on maintaining consistency in the manufacture of sieves. This allows the comparison of sieving operations provided the materials and conditions of the sieving are also comparable. The focus of many practitioners of sieving has been on standard procedures to maintain reproducibility and consistency.

Sieve Agitation

Particles placed on a sieve may not sort or pass through the openings unless some form of agitation is used. Typically, a large mass of soil placed on a sieve

will allow particles to bridge, thus restricting their passage through the openings. Agitation breaks the bridges, shuffles the particles and provides an opportunity for particles to present themselves to an opening.

An undersize particle may still fail to pass through a sieve. Figure 1 illustrates how identically shaped particles may approach the aperture at different angles. Some angles may allow passage of the particle while others may restrict passage. Agitation increases the number of times that a particle approaches the aperture and the velocity of approach and alters the orientation of the particle as it approaches the aperture. The first two factors depend on shaking intensity and competition among particles. The third factor depends on the shape of the particle and the shape of the sieve opening. These factors influence not only the speed with which fractionation occurs, but the retention of specific particles.

Alternative commercial instruments attempt to agitate the particles in different ways. Vibration is commonly used, either as a jarring action or an oscillatory motion. This motion may have a large or small amplitude and may be restricted to horizontal or vertical motion. The efficiency of separation usually increases as vibration amplitude increases, but it may reach a maximum. Efficiency declines as the increased agitation merely serves to suspend particles without giving them an opportunity to pass through an aperture.

One means of agitating particles is by displacing the fluid (air or water) surrounding the particles. In the case of air, this may involve ultrasonic oscillation or mechanical flow of air counter to the direction of sieving. In an extreme case, the sieve may be placed in

**Figure 1** How particle shape influences the efficiency of sieving by delaying passage through the sieve.

a vertical orientation as air flow lifts the particles and attempts to pass through the sieve. Particles retained on the sieve would need to be mechanically removed. Such a manipulation could be maintained in operation continuously.

Sieved Materials

The particle influences the time and efficiency of sieving. Issues relate to the sample's mass, particle size distribution, particle density, particle shape, friability, the tendency to aggregate and electrostatic properties. Specific procedures have been developed for particular materials.

Obtaining a representative sample or subsample for sieve analysis is a key step; this is a particular issue where nonuniformity is extreme or segregation of the sample may occur. It may sometimes be necessary to settle for reproducible sampling with the goal of making comparisons on a relative basis.

Sample mass influences the efficiency of sieving and the time needed for a sieving operation. At high loadings, blinding of the sieve may be more important as well as increased breakdown of friable samples.

Particle size distribution has several effects on the efficiency of sieving. These effects, if they exist, may depend on the choice of sieves. Particles which are slightly oversize may lodge in the sieve, blocking the aperture from participating in the sieving process. This 'blinding' of the sieve reduces the overall efficiency of sieving or increases the time needed to achieve separation.

Sample friability can also influence separation. Friability is the tendency of particles to break apart. The process of agitation and sieving may change the particle size distribution for friable samples. Longer sieving times or larger amplitude agitation increase these effects. Ultimately, the goal of the sieving operation must be compared to the effect of sieving on the underlying size distribution.

Time Dependence of Sieving

Sieving Curves

The mass passing through the sieve can be observed by collecting this material on a balance or strain gauge. This can be done manually or the sensor can be connected to a computer and the progress of sieving continuously monitored as a function of time. The graph of mass remaining on the sieve or the mass that has passed the sieve is referred to as a sieving curve (Figure 2). The graph shown in Figure 2 shows the mass passing through the sieve as a function of time. Note that complete separation may never be achieved.

Sieving Equations

Sieving curves like that shown in Figure 2 are the result, in part, of particle shape. Extracting this information requires a quantitative description of the sieving curve. Models describing the sieving curves can be classified as empirical or mechanistic. The most common empirical model uses a power

Figure 2 Example of three sieving curves modelled with the equation $P = 100\% [1 - \exp(-kt^n)]$, $n = 0.8$. Dashed line, $k = 0.025$; dotted line, $k = 0.050$; continuous line, $k = 0.10$.

function. The rate at which material passes through the sieve for short times is nearly constant and can be expressed by a power function model given as:

$$M = at^b$$

where M = cumulative mass of the material passed at sieving time t (grams), t = sieving time (seconds), b = a constant nearly equal to 1 and a = sieving rate constant, with units of $g\ s^{-1b}$. This model has had some practical utility but its validity in describing data, even for short times, is questionable and depends on how the data are truncated.

One mechanistic model starts by assuming that the probability of particle passage at time t is directly proportional to the mass of material on the sieve. Thus, the mass of material remaining (M_t) at sieving time t is described in differential form by:

$$\frac{dM_t}{dt} = -k(M_t - M_r)$$

where M_t = total mass of the material remaining on the sieve at time t (grams), M_r = material mass which does not pass the sieve (i.e. the sieve residue after infinite sieving time) (gram) and k = passage probability of the material with a given size at time t , or passage rate factor (s^{-1}).

This model assumes that, after a time, k becomes independent of time and particle size. This occurs when the smallest particles have passed through the sieve and those left on the sieve are of a size close to the sieve opening. However, the sieving constant (k) is not guaranteed to be constant. For example, it may change with the depth of material on the sieve and hence change as M changes. Thus, one difficulty in using the above equation lies in describing how k changes with experimental conditions or time.

Integrating the above equation (setting $M_r = 0$) with the application of initial conditions yields:

$$M = M_0(1 - e^{-kt})$$

where M = cumulative mass of material passed at sieving time t (grams) and M_0 = cumulative mass of the material that would pass at infinite sieving time (grams). Note that $M + M_t = M_0$. The rate constant can be determined empirically or deduced from physical principles. In the latter case k is defined as:

$$k = A[1 - 2R(1 - f_s)/D]^2$$

where A is a constant depending on the sieve and sieving conditions, R is a radius of the particle, D is the sieve opening and f_s is a grouping of factors that describe particle shape. Tests of this model have not been extensive. It should work best for longer times.

An alternative or modified proportional model has been used with some success over a wide range of sieving times. This model starts by assuming that the constant k in the differential equation above is a function of time, $k = k^*/t^m$. Then the differential equation can be written as:

$$\frac{dM_t}{dt} = -\frac{k^*(M_t - M_r)}{t^m}$$

where k^* = passage probability of the material with a given size at time t , or passage rate factor, (s^{-n}) and $n = 1 - m$ where m is a constant.

Upon solving this equation for M and substituting $1 - n$ for m , the resulting model is:

$$M = M_0(1 - e^{-k^*t^n})$$

This model appears to describe both the initial and long time sieving behaviour. It is empirical in nature, so its coefficients need to be related to particle morphology or other sample characteristics.

Sources of Error

The Sample

The major concern with sieving operations is the efficiency and time of each sieving step. This becomes particularly important when we use a nest of sieves to perform several separations simultaneously. The use of words such as effective or nominal diameters with sieves is in recognition of the imperfect separation that may occur. What is less readily recognized is that the sample may contribute to imperfect separation.

Placement of a soil sample on a sieve does not result in instantaneous separation. Several factors influence the time to achieve a fixed level of segregation. These factors include sample size, shaking intensity, particle shape, particle size and hole geometry. No one set of sieving times applies for all conditions, but for many soils with small samples (~ 100 g) a waiting time of about 3–5 min for coarse fractions and 10 min for fine fractions gives acceptable results. A typical nest of sieves (with 3 in (7.5 cm) diameter) operating for at least 15 min is desirable for separation. Since samples vary in their sieving characteristics, it is best to run a trial sample at several times. This is particularly true with a nest of sieves to ensure adequate separation past the smallest sieve opening.

The single most important factor changing the efficiency of sieving is the initial sample mass. It is faster and more efficient to split a large sample into several smaller ones. A useful rule of thumb is to keep the depth of material on the sieve to less than 1 cm. A better rule is to run a test sieving curve. In general, this will show that as the sieve opening decreases smaller masses are needed. For 8 in (20 cm) diameter sieves these typically range from 200 to 30 g for sieve openings varying from 2 mm to 45 μm .

Particle shape also influences the efficiency of sieving. Rougher surfaces with elongated shapes are expected to require longer sieving times than smooth surfaces with a more spherical shape. It may be possible to use equations like the one presented earlier to predict the sieving rate constant. However, the inverse problem of determining the particle shape from sieving curves appears to be ambiguous.

Sieve Construction and Cleaning

The manufacture of sieves is subject to error. This error takes the form of a variation in aperture opening within a sieve as well as from sieve to sieve. This error also varies with the size of the opening, with the coarser sieves generally being more consistent. It is expected that for the finer sieves (less than 100 μm), this error could approach 10%. Thus, all sieve openings represent nominal diameters. The determination of the diameter of material that passes a particular sieve must be determined by calibration, as discussed in the next section.

Sieve cleaning represents one means of ensuring the reproducibility of a sieve. This typically involves use of a brush with the coarser sieves. Finer sieves may require reverse flushing with water or use of an ultrasonic cleaning bath. Ultimately, sieves must be inspected at periodic intervals to make sure that the mesh has not been distorted or damaged in use.

Calibration

A sieve calibration is used to establish the size of separation achieved by a particular sieve. This involves the use of standard materials and microscopic examination of the material passing through the sieve. The material is placed on the sieve and sieving proceeds until the mass passing appears unchanged. The material which has passed is examined under a microscope to determine the size of particles. This

information is used to find an average equivalent volume diameter which represents the effective size of the sieve.

Conclusion

Sieving is a valuable and widely used tool for both sorting and particle size determination. It is a relatively inexpensive procedure that, with the use of standard methods, can provide reproducible results. The use of sieves for novel materials requires the determination of sieving curves under a variety of conditions such as loading. These curves are used to optimize the conditions for efficient sieving. Even where only slight variations in the material to be analysed exist, it may be desirable to determine the appropriate sieving conditions rather than relying on standard methods.

Split Flow Thin Cell (SPLITT) Separation

C. Contado, University of Ferrara, Ferrara, Italy

Copyright © 2000 Academic Press

Introduction

SPLITT fractionation (SF) is a relatively new family of separation techniques primarily – but not exclusively – applicable to macromolecules and particles. The SF techniques utilize a thin ribbon-shaped flow cell and achieve fractionation by differential transport across the thin (transverse) axis of the cell. Since the cell is only a few hundred micrometres thick, the separation path – which may be less than the nominal channel thickness – is extremely short and the separative transport is correspondingly rapid. Separation is typically accomplished in only a few minutes. This is a particularly valuable feature for example for fragile species that must be fractionated rapidly to avoid degradation (e.g. biological samples). The fluid that carries dissolved or suspended components through the SPLITT cell is divided at both ends by thin flow splitter elements (see Figure 1). The inlet splitter element allows for the smooth merging of two incoming laminae, one carrying the suspended feed material and the other generally containing only the pure car-

rier liquid. Differential transport of feed components between the two laminae (after they are brought into contact) then occurs as a result of a transverse driving force or gradient. At the outlet end, the flowing liquid volume is divided at a predetermined position by a second splitter element, thus producing two sub-streams that are enriched or depleted in the desired components as a result of the differential transport.

Both preparative and analytical fractionation process can occur in the SPLITT cells, depending on the injection procedure. A continuous (CSF) process of feeding the cell is advantageous for preparative fractionation (gram, kilogram), offering rapid throughput, minimum holdup volumes, and a sharp separative cut off; examples of continuous fractionation can be found in the separation of mineralogical, industrial and food samples.

The analytical version of SPLITT fractionation (ASF) is often more practical to operate. The injection of discrete pulses can be made, if desired, to follow one another in close sequence. In this use, separation is performed for the measurement of quantitative properties of sample components and the fractionation is termed 'analytical SPLITT fractionation';

Figure 1 Side view of a generic SPLITT cell.

examples of quantitative determinations include diffusion coefficients of proteins, settling velocity and the relative content of oversized particles above a cutoff diameter in a particulate material. Moreover because of its ease of theoretical interpretation, the SPLITT cell can be used for the rapid measurement of transport-related properties such as particle size and particle size distribution. The throughput of SF is proportional to many variables such as the sample concentration in the feed stream, the volumetric flow rate of the sample stream, the applied field strength and the SPLITT cell area. For preparative applications there is obviously a trade-off between the resolution and throughput in the operation of SF: maximizing the throughput and maintaining an acceptable resolution is the common choice.

The effectiveness of the SPLITT process can be modulated by simply varying the flow rates of the inlet and outlet substreams, which determine the position of the inlet splitting plane (ISP) and the outlet splitting plane (OSP) and controlling the thickness of the transport region; sometimes, unwanted displacements of a few tens of micrometres may be difficult to discern but they are sufficient to interfere with effective separation. In some cases, the efficiency of the SPLITT process can be controlled by altering the strength of the field or gradient driving the separative transport.

The efficacy of SF separation depends instead, on the hydrodynamic integrity of the SPLITT cell. Effective separation is based in fact, on two central requirements:

- there must be no hydrodynamic mixing across stream planes; and
- the splitters must be absolutely perfectly aligned so that they are capable of splitting the film of flowing liquid evenly along the stream plane.

Success in fulfilling these requirements is not easy to judge because of the thinness of the cell and the shortness of the transport path.

The selectivity of SPLITT fractionation comes from the applied force. The principal transverse driving forces used include gravity, centrifugation, diffusion, electrical potential gradients, magnetic gradients and hydrodynamic lift forces. The geometry of all the different cells is similar to that depicted in Figure 1, except for the curvature characteristic of the centrifugal SPLITT cell.

The simplicity of the SPLITT cell leads to rather rigorous theoretical guidelines on the conditions necessary to achieve a given level of separation.

Theory

The theory of separation by SPLITT cell was formulated by J. C. Giddings in terms of experimentally controllable flow rates in the inlet and outlet substreams and it has been developed and implemented through the years; SPLITT fractionation theory can now be found in numerous publications. The separation is performed inside a thin channel, where the behaviour of a sample particle depends on the balance between the external force field and frictional forces (as for field flow fractionation techniques (FFF)), combined with the action of the fluxes operative within the cell.

In Figure 1 the sample, suspended in a suitable carrier fluid, is introduced through the top inlet a' at a predetermined volumetric flow rate $\dot{V}(a')$. At the same time, pure carrier fluid enters through the bottom inlet b' at a flow rate $\dot{V}(b')$; where the two inlet streams join to form a single stream we have the ISP. When the fluid stream reaches the end of the channel, it is mechanically divided into two fractions by the outlet splitter.

The differential displacement of the particles occurs towards wall B, based on the driving force exerted on each type of particle by the applied field and the frictional resistance offered by the carrier fluid to particle motion. Thus different types of particle occupy different laminae while the flow through the channel displaces them axially towards the outlet end.

The total volumetric flow rate \dot{V} in the channel can be written both in terms of inlet flow rates or outlet flow rates

$$\dot{V} = \dot{V}(a') + \dot{V}(b') = \dot{V}(a) + \dot{V}(b) \quad [1]$$

and since the walls A and B are parallel and their dimensions much larger than w (thickness) and b (width), the velocity profile is essentially two-dimensional (see Figure 2). The mean fluid velocity \bar{v} can be computed as \dot{V}/bw , and the velocity parabolic profile across the cell thickness is described by the equation:

$$v\left(\frac{x}{w}\right) = 6\bar{v}\frac{x}{w}\left(1 - \frac{x}{w}\right) = 4v_{\max}\frac{x}{w}\left(1 - \frac{x}{w}\right) \quad [2]$$

where v_{\max} is the maximum fluid velocity found at the midplane ($x = w/2$) of the cell.

By looking at the flow stream components (see Figure 1) it is possible to find a relation which takes into account the fluid flow proceeding in the transport layer $\dot{V}(t)$:

$$\dot{V} = \dot{V}(a') + \dot{V}(t) + \dot{V}(b) \quad [3]$$

Figure 2 Upper view of the 'Splitter' used in the gravitational SPLITT cell.

$\dot{V}(t)$ can be obtained by combining eqns [1] and [3] as:

$$\dot{V}(t) = \dot{V}(a) - \dot{V}(a') = \dot{V}(b') - \dot{V}(b) \quad [4]$$

The separation of sample components is achieved, as previously described, by their different rates of transport toward the opposite wall B under the influence of the transverse field. It is important to be able to calculate the distance that a component has to travel. The ratio of sample flow rate $\dot{V}(a')$ to the total flow rate \dot{V} defines the position of the ISP as distance w_a , from wall A:

$$\frac{\dot{V}(a')}{\dot{V}} = 3\frac{w_a^2}{w^2} - 2\frac{w_a^3}{w^3} \quad [5]$$

The feed stream is then confined to the lamina thickness w_a , between wall A and the ISP.

By assuming that, during their residence in the SPLITT cell, the particles are driven from wall A to wall B at constant velocity U , the volumetric flow rate $\Delta\dot{V}$ of the lamina traversed by a particle is simply given by

$$\Delta\dot{V} = bLU \quad [6]$$

which contains the physical dimensions of the channel b , and L (length); U is the velocity of the induced transverse transport. In fact, a number of different driving forces have been utilized to implement CSF: gravitational, centrifugal, magnetic, electrical. U assumes different expressions depending on the field inducing the transverse transport, i.e.

$$U_{\text{gravitational}} = \frac{gd^2|\Delta\rho|}{18\eta_o} \quad [7]$$

$$U_{\text{centrifugal}} = \frac{\omega^2 rd^2\Delta\rho}{18\eta_o} \quad [8]$$

$$U_{\text{magnetic}} = \frac{\Delta\chi\Delta H^2 d}{48\eta_o} \quad [9]$$

$$U_{\text{electric}} = \mu E \quad [10]$$

where d is the particle diameter (assumed spherical), $\Delta\rho$ is the difference between particle density ρ_s (compact particles) and carrier density ρ_l , η_o is the viscosity of the carrier, g is the acceleration of gravity (earth field eqn [7]); ω is the angular velocity (rad s^{-1}) and r is the radius of the rotation (centrifugal acceleration eqn [8]); $\Delta\chi$ is the difference between the magnetic susceptibilities of the particles, χ_p , and the carrier, χ_l , and ΔH is the drop in magnetic field strength (eqn [9]); μ is the electrophoretic mobility and E is the electric field strength (eqn [10]). In some cases, experimental studies have been based on diffusive transport or by using hydrodynamic lift forces (which can be used in unique ways because of their nonuniformity).

In order to settle whether particles exit the channel through outlet a or b, the relative values of $\Delta\dot{V}$ and $\dot{V}(t)$ are of critical importance. For a sample introduced close to the ISP, particles exit from outlet a if:

$$\Delta\dot{V} \leq \dot{V}(t) \quad [11]$$

and from outlet b if:

$$\Delta\dot{V} > \dot{V}(t) \quad [12]$$

In the case of a SPLITT cell operating under a gravitational field, the relation which allows one to set the diameter cutoff of a spherical solid particle can be obtained by combining eqns [4], [6] and [7]. In fact, if $\dot{V}(t) = \Delta\dot{V}$ and:

$$\Delta\dot{V} = \frac{bLgd^2|\Delta\rho|}{18\eta_o} \quad [13]$$

then the diameter at which 50% of the particles exit outlet b is called the cutoff diameter d_c , expressed as:

$$d_c = \sqrt{\frac{18\eta_0(\dot{V}(a) - 0.5\dot{V}(a'))}{bL\Delta\rho g}} \quad [14]$$

in which only half of $\dot{V}(a')$ is considered (cf. eqn [4]). Once d_c has been chosen for a given channel, the difference between $\dot{V}(a)$ and $0.5\dot{V}(a')$ is set according to eqn [14]. However, the two constituents flow rates $\dot{V}(a)$ and $\dot{V}(a')$ are not uniquely defined by this equation, but some criteria useful for setting the flow rates are available in the optimization of SPLITT operations literature. In general, in order to obtain a separation with a good resolution, the practical rule which states the following necessary but not sufficient condition:

$$\dot{V}(b') \gg \dot{V}(a') \quad \text{or} \quad \dot{V}(a) \gg \dot{V}(b) \quad [15]$$

can be followed. This condition ensures that regions I and II will be narrow, which automatically increases the transport region, i.e. the cell space in which the separation process occurs. For maximum resolution, typical experimental conditions, are chosen to obtain a $\dot{V}(a')/\dot{V}(t)$ ratio within 0.1–0.3. From a theoretical point of view, the high resolution in the operative *transport mode* is, as already stated, contingent on compression of the feed sub-stream, a' , into a thin lamina near wall A, and the sharpness of the separation, as in chromatography, can be judged by the number N of the theoretical plates generated during transport. Generally, for field (gravitational) driven migrations, the effective N is given by the ratio of two energies:

$$N = \frac{Fw_t}{2kT} = \frac{\pi d^3 \Delta\rho g w_t}{12kT} \quad [16]$$

where F is the force on the particle inducing its transport, w_t the length of the transport path, and kT the thermal energy. Generally values of $N \geq 10^2$ are required to assure achievable resolution, and each type of macromolecule or particle should be checked against this criterion.

Resolution in SF can be related to channel flow rates, defining an index which measures the relative breadth of the unresolved region. It has been demonstrated that for sedimentation particles the equation of the resolving power has the following form:

$$\frac{d_1}{\Delta d} = \frac{d_1}{d_1 - d_0} \cong 2 \frac{\dot{V}(a)}{\dot{V}(a')} \quad [17]$$

where d_0 and d_1 are respectively the diameters of the particles exiting from a and b. The particles falling between these two sizes (d_1 and d_0), which are not fully resolved, exit from both outlets in different proportions, so the difference should be small. According to eqn [17] the ratio of $\dot{V}(a)$ to $\dot{V}(a')$ allows control of the range of unresolved particles which exit both outlets a and b.

Specific Applications

Determination of the Diffusion Coefficient D

CSF and ASF can be successfully applied to the separation of macromolecules such as proteins and liposomes. The transport region in this case is seen as a diffusion barrier, which acts as a dialysis membrane. In order to be able to determine the diffusion coefficient D , an important parameter useful for characterization of the sample components, the theory has to be looked at in a deeper way, with equations which explicitly contain D .

If a component enters inlet a' as a steady stream and its transport through the SPLITT system is governed by the simultaneous displacements of diffusion and parabolic flow, mass conservation requires that:

$$\frac{\partial c}{\partial t} = -v(x)\frac{\partial c}{\partial z} + D\left(\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial z^2}\right) \quad [18]$$

$\partial c/\partial t$ is the rate of change of concentration at an arbitrary point within the channel, x is the transverse distance into the cell measured from wall A, z is the distance into the channel along the length measured from the inlet splitter and v is the local stream velocity. In order to simplify eqn [18], it can be observed that all transverse transport in the channel occurs by diffusion and that all the components are transported along the cell (z -direction) by convection, so that the diffusion term ($D\partial^2 c/\partial z^2$) can be neglected.

Moreover, if the system operates in CSF mode, the component concentrations throughout the cell will attain a steady state, i.e. $\partial c/\partial t = 0$, so that eqn [18] reduces to:

$$\frac{\partial c}{\partial z} = \frac{D}{v(x)}\left(\frac{\partial^2 c}{\partial x^2}\right) \quad [19]$$

where $c(x, z)$ is subject to the boundary conditions:

$$\begin{aligned} c(x, 0) &= c_0 & \text{for } 0 \leq x \leq w_a \\ c(x, 0) &= 0 & \text{for } w_a \leq x \leq w \\ \partial c/\partial x &= 0 & \text{for } x = 0 \text{ and } x = w \text{ at all } z \end{aligned}$$

In order to calculate D , a dimensionless diffusion time $\tau_D = Dt^\circ/w^2$ has been developed. The parameters t° and w^2 are known because w is fixed by the geometry of the channel and t° is the elution time of a species dispersed in the total volume of the channel and is related to the total flow rate \dot{V} by:

$$t^\circ = \frac{V^\circ}{\dot{V}} = \frac{bLw}{\dot{V}} \quad [20]$$

where V° is the cell void volume expressed as a product of channel dimensions b , L and w . The dimensionless time parameter t° is thus related to D , \dot{V} , and the channel dimensions by:

$$\tau_D = \frac{Dt^\circ}{w^2} = \frac{DbL}{w\dot{V}} \quad [21]$$

Consequently D is given by:

$$D = \frac{w\dot{V}\tau_D}{bL} \quad [22]$$

This equation is used to obtain experimental D values, once τ_D is found. The total procedure requires the following steps: (i) to compute theoretically the concentration profile $c(x, L)$ over the lateral coordinate x at outlet ($z = L$) by using the Crank-Nicolson numerical method. In this way, the retrieval of a component at each outlet substream F_a (in i) and F_b (in ii) can be calculated from $c(x, L)$; (ii) to construct a graph of F_a versus τ_D for different $\dot{V}(a)/\dot{V}$ ratios; (iii) to determine experimentally the retrieval factor at outlet sub-stream a (F_a) from the relative strength of the detector signal (this value depends on the flow ratio $\dot{V}(a)/\dot{V}$ used in the experiment); (iv) to compute the correspondent τ_D value from the graph F_a versus τ_D by finding the correspondence between the experimental and theoretical F_a values; (v) to use eqn [22] to calculate D using the τ_D value, and the geometrical dimensions b , L , w and \dot{V} .

Effect of Particle Shape and Density in the Gravitational SPLITT

The SPLITT cell has been largely applied for the separation of environmental samples. Since the natural matter particles have different properties (porosity, density, shape), the basic SPLITT equations have to be revised to fit the relevant particle properties.

The basic relationship for the SPLITT cell, previously derived (see eqn [6]) can be written as:

$$\Delta\dot{V} = \dot{V}(t) = bLU_{\text{gravitational}} \quad [23]$$

By recalling the basic properties of the sedimentation process different expressions can be obtained, which contain the density parameter. During the SPLITT fractionation, under a gravitational field, the sample components are subject to two forces: the gravitational force $F_g = m_{\text{eff}}g$ and the frictional force $F_f = fU$ (m_{eff} is the effective mass, and f the friction coefficient). Usually, the stationary state is established very rapidly and the two forces balance each other out and thus:

$$U = m_{\text{eff}} \frac{g}{f} \quad [24]$$

Spherical particles In the case of compact spherical particles, by assuming that the particles do not undergo any shrinking or swelling $m_{\text{eff}} = m - m_b$ or $m_{\text{eff}} = V_s\rho_s - V_s\rho_l$, where m is the real mass and m_b the buoyant mass while V_s and ρ_s are, respectively, the volume and density of the particle and ρ_l the density of the liquid. More explicitly

$$m_{\text{eff}} = \frac{1}{6} \pi d^3 |\Delta\rho| \quad [25]$$

The $||$ accounts for positive or negative mass values in eqn [25] corresponding, respectively, to a falling or a floating particle. The friction coefficient f can be expressed by Stokes law $f = 3\pi\eta d$, where η is the viscosity of the suspension fluid, which can be approximated by the carrier viscosity, η_0 . By combining eqns [23], [24] and [25] one obtains the classical expression (see eqn [13]):

$$\dot{V}(t) = \frac{bLgd^2|\Delta\rho|}{18\eta_0} \quad [26]$$

In the case of porous particles, porosity is defined as:

$$\varepsilon = \frac{V_p}{V_s + V_p} = \frac{V_p}{V_{\text{tot}}^p} \quad [27]$$

where V_p is the volume of the pore, V_s the volume of the solid and V_{tot}^p the total volume of the particle. Then eqn [25] changes into:

$$m_{\text{eff}} = \frac{1}{6} \pi d^3 (1 - \varepsilon) |\Delta\rho| \quad [28]$$

and the correspondent eqn [26] into:

$$\dot{V}(t) = \frac{bLgd^2(1 - \varepsilon)|\Delta\rho|}{18\eta_0} \quad [30]$$

The porosity can be expressed also in terms of ‘apparent density’:

$$\rho_{\text{app}} = (1 - \varepsilon)\rho_s + \varepsilon\rho_l \quad [31]$$

from which the differential apparent density is defined as:

$$\Delta\rho_{\text{app}} = \rho_{\text{app}} - \rho_l \quad [32]$$

By combining $\Delta\rho = \rho_s - \rho_l$ with eqns [31] and [32] one has:

$$\Delta\rho_{\text{app}} = (1 - \varepsilon)\Delta\rho \quad [33]$$

which can be substituted in eqn [30].

When the ‘mass porosity’ is available:

$$p = \frac{V_p}{m} \quad [34]$$

where m is the real mass of the particle, i.e. $m = V_s\rho_s$ and by using eqn [27] one can show that:

$$\left(\frac{1}{p\rho_s + 1}\right) = (1 - \varepsilon) \quad [35]$$

which gives:

$$\dot{V}(t) = \frac{bLgd^2|\Delta\rho|}{18\eta_o} \left(\frac{1}{p\rho_s + 1}\right) \quad [36]$$

Alternatively, one can employ the ‘bulk density’, which is the ratio between the amount of the porous material, m_{tot} , and the total volume occupied by the packed particles V_{tot} including both the inter-particle volume, V_{ex} , the particle volumes, V_p^{tot} (total volume of the pores) and V_s^{tot} (total solid volume):

$$\rho_{\text{bulk}} = \frac{m_{\text{tot}}}{V_p^{\text{tot}} + V_s^{\text{tot}} + V_{\text{ex}}} = \frac{m_{\text{tot}}}{V_{\text{tot}}} \quad [37]$$

In this instance, both the ρ_{bulk} and ε_{ex} depend on the degree of packing. The relative apparent density, $\Delta\rho_{\text{app}}$ can be obtained by combining eqns [33] and [37]:

$$\Delta\rho_{\text{app}} = \frac{\rho_{\text{bulk}}}{\rho_s(1 - \varepsilon_{\text{ex}})} \Delta\rho \quad [38]$$

From eqn [33] it is apparent that, in this case, one must know the value of ε_{ex} under the same experimental conditions which ρ_{bulk} was determined. Lacking this information, it is only possible to make a rough estimate of $\Delta\rho_{\text{app}}$.

Nonspherical particles There are two main effects to be accounted for with nonspherical particles: the first is related to the particle volume expression and the second to Stokes Law. The parameter d contained in eqn [7] has to be changed depending on the kind of data available.

The first effect is accounted for by using the volume equivalent diameter, i.e. the diameter of a sphere having the same particle volume V_{sp} , i.e. $d_v = \sqrt[3]{(6V_{\text{sp}}/\pi)}$ instead of the sphere diameter, d . This quantity sometimes can be related to true geometrical dimension of the particle if its geometry is known.

An irregular shape affects the behaviour of the particle while it is moving within the fluid. Stokes Law takes account of this by substituting the diameter d with the ‘drag diameter’, i.e. the diameter of a sphere having the same resistance to the motion within the fluid

$$f = 3\pi\eta_o d_d \quad [39]$$

In order to conclude this section, an appropriate combination of all the above cases is necessary for irregular porous particles.

List of Symbols

a	= aspect ratio
b	= width of the SPLITT channel
d	= diameter of the sphere
d_c	= cutoff diameter
d_d	= drag diameter
d_v	= diameter of an equivalent sphere
D	= diffusion coefficient
E	= electrical field
f	= frictional coefficient
F_a	= retrieval of a component from outlet a
F_b	= retrieval of a component from outlet b
F_g	= gravitational force
F_f	= frictional force
g	= gravity acceleration
h	= thickness of the transport layer
h_c	= high of a cylindrical particle
L	= length of the SPLITT channel
m	= real mass of a particle
m_b	= mass corrected for buoyancy
m_{eff}	= effective mass
m_{tot}	= total mass of all particles present in the container
p	= mass porosity
r	= radius of rotation
t_r	= crossing time, i.e. the time a particle takes to pass through the cross sectional area bh in the h -direction.

U	= particle migration velocity
\bar{v}	= mean fluid velocity
v_{\max}	= maximum fluid velocity
\dot{V}	= total volumetric flow rate through cell
$\dot{V}(a')$	= volumetric flow rate at outlet a'
$\dot{V}(b')$	= volumetric flow rate at outlet b'
$\dot{V}(a)$	= volumetric flow rate at inlet a
$\dot{V}(b)$	= volumetric flow rate at inlet b
$\dot{V}(t)$	= volumetric flow rate of the transport region
V_{ex}	= external volume between particles
V_{p}	= pore volume of a particle
$V_{\text{p}}^{\text{tot}}$	= total pore volume for all the particles
V_{s}	= volume of the solid part of a particle
$V_{\text{s}}^{\text{tot}}$	= total solid volume for all the particles
V_{Sp}	= volume of a sphere
V_{tot}	= total volume occupied by all particles present in the container
$V_{\text{tot}}^{\text{p}}$	= total volume of a particle
w	= thickness of the SPLITT channel
$w_{a'}$	= thickness of the fluid lamina between wall A and ISP
w_t	= thickness of the transport region
χ_l	= magnetic susceptibility of the carrier
χ_p	= magnetic susceptibility of a particle
ε	= internal porosity
η	= suspension viscosity
η_o	= carrier viscosity
μ	= electrophoretic mobility
ρ_{app}	= apparent density
ρ_{bulk}	= bulk density
ρ_l	= density of the liquid
ρ_s	= density of the spherical particle
ω	= angular velocity
τ_D	= dimensionless diffusion time

Principle

Field-flow fractionation (FFF) is one of the important analytical methodologies, suitable for the separation and characterization of particles in the submicron

and micron ranges. The effective field generates the flux of the separated particles and forms a concentration gradient of each particular species across the ribbon-shaped separation channel. The concentration gradients are counter-balanced by a diffusion flux. At equilibrium, a stable concentration distribution of each particular species is established in the direction across the channel. Simultaneously, a flow velocity profile is formed across the channel due to the viscous

Figure 1 Schematic representation of the general principle and of the experimental arrangement of FFF: (1) carrier liquid reservoir; (2) pump; (3) injector; (4) separation channel; (5) detector; (6) computer; (7) external field; (8) hydrodynamic flow. Detail shows the schematic representation of two fundamental separation mechanisms: polarization FFF and focusing FFF.

drag in the longitudinal flow of the carrier liquid. As a result, each particle is carried along the channel with a velocity corresponding to an instantaneous position of the particle within the flow velocity profile. The carrier liquid thus elutes each species with a mean velocity which corresponds roughly to the position of the centre of gravity of the field-induced concentration distribution across the channel of that species. This principle is schematically demonstrated in Figure 1.

The separation is usually governed by the differences in size of the separated components of a poly-disperse sample. If the appropriate relationship between the retention parameters and the size of the particles is known or found empirically by using a suitable calibration procedure, the fractograms can be used to calculate the particle size distribution (PSD) and the average values of the particle size of the fractionated species. However, the intensive properties (such as the electrical charge, density, etc.) can influence the separation based on size differences.

Theory of Separation

Two distinguished separation mechanisms, either *polarization* or *focusing*, govern the separation. The separated particles can be differently compressed to

the accumulation wall of the channel according to their sizes or focused at different levels across the channel according rather to an intensive property (see Figure 1).

The polarizing field force, F , and the velocity of the field-induced migration of the fractionated particles, U , are usually constant and independent of the position in the direction of the field action:

$$F \neq 0 \text{ and } U \neq 0 \text{ within } 0 < x < w$$

where w is the thickness of the FFF channel in the direction of the field action (x -axis); $x = 0$ is situated at the accumulation wall of the channel. The steady-state concentration distributions of the sample components across the channel are exponential:

$$c_i(x) = c_i(0) \exp\left(-\frac{x}{l_i}\right)$$

where $l_i = D_i/U_i$ is the mean layer thickness, D_i is the diffusion coefficient and c_i is the concentration of the i th species. Larger particles are usually concentrated more closely to the accumulation wall. As a result, the order of the elution is from the small species to larger ones.

The focusing field force and the corresponding velocity U are position dependent:

$$\begin{aligned} F &= f(x), \quad U = f(x) \quad \text{within } 0 < x < w \\ F(x) &= 0, \quad U(x) = 0 \quad \text{for } x = x_{\max}, \quad 0 < x_{\max} < w \end{aligned}$$

The coordinate x_{\max} corresponds to the position at which the concentration distribution of a focused sample is maximal. Each sample component is focused around its proper x_{\max} position. The steady-state concentration distribution is close to the Gaussian distribution:

$$c(x) = c_{\max} \exp\left[-\frac{1}{2kT}\left(\frac{dF(x)}{dx}\right)_{x=x_{\max}}(x-x_{\max})^2\right]$$

where k is the Boltzmann constant and T is the temperature. In some cases the polarization and the focusing mechanisms can act simultaneously.

As mentioned above, a real separation channel is usually ribbon-shaped. However, two parallel infinite planes represent a good approximation of this form. The flow velocity profile established in such a hypothetical channel is parabolic under isoviscous conditions:

$$v(x) = \frac{\Delta P x(x-w)}{2L\mu}$$

where $v(x)$ is the linear velocity of a flow streamline at the position x , ΔP is the pressure drop along the channel of length L , and μ is the viscosity of the carrier liquid.

To describe conveniently the retention of the separated particulate species, the dimensionless retention ratio R is defined:

$$R = \frac{\int_0^w c(x)v(x) dx \int_0^w dx}{\int_0^w c(x) dx \int_0^w v(x) dx}$$

R is the ratio of the average velocity of a retained sample component divided by the average velocity of the carrier liquid. The integration gives the relationship for the polarization FFF

$$R = 6\lambda \left(\coth\left(\frac{1}{2\lambda}\right) - 2\lambda \right)$$

where $\lambda = l/w$. The analogous approximate relationship for the focusing FFF is:

$$R = 6 (\Gamma_{\max} - \Gamma_{\max}^2)$$

where $\Gamma_{\max} = x_{\max}/w$, is the dimensionless coordinate of the maximal concentration of the focused zone. R can be experimentally determined as the ratio of the retention volume (or the retention time) of an unretained sample component (equal to the volume of the channel) divided by the retention volume (retention time) of the retained sample component. The simple and known relationship between the λ and the particle size make it possible to calculate the PSD from the experimental retention data.

Each fractionation is based on transport processes which lead to the formation of the concentration gradients. From the thermodynamic point of view, the general entropic tendency of a closed system is to erase such gradients by molecular motion. As a result, the spreading of the zones due to dispersion processes occurs. The zone spreading can be quantitatively described by the height equivalent to a theoretical plate H :

$$H = L \left(\frac{\sigma}{V_R} \right)^2$$

where V_R is the retention volume and σ is the standard deviation of the zone of uniform size particles. The elution curve (fractogram) of a polydisperse sample thus reflects the contribution of the spreading processes superposed over the fractionation according to the PSD.

In order to calculate a true PSD from the experimental raw fractogram, a correction for the zone

spreading should be applied. It is based on the deconvolution of an experimental fractogram $h(V)$ of a polydisperse particulate sample which is a superposition of the true PSD $g(Y)$ and the spreading function $G(V, Y)$ representing the zone of uniform particles having the elution volume Y :

$$h(V) = \int_0^\infty g(Y)G(V, Y) dY$$

where V and Y are then the elution volumes. This equation, called the Tung integral equation, is the basis for all well-known correction methods and can be solved analytically under the condition that the spreading function is uniform. In this case, the convolution integral to be solved is:

$$h(V) = \int_0^\infty g(Y)G(V - Y) dY$$

In a number of practical cases, the spreading function can be approximated by the normal Gaussian function. The application of the correction of an experimental fractogram is demonstrated in **Figure 2**.

The true PSD can be expressed as a number of the particles of a given diameter n_i relative to the number of all the particles in the sample:

$$N_i = \frac{n_i}{\sum_0^\infty n_i}$$

or as the mass of the particles m_i of a given diameter d_i relative to the total mass of the sample:

$$M_i = \frac{m_i}{\sum_0^\infty m_i}$$

The PSD can be used further to calculate various average particle sizes such as the mass average particle diameter:

$$\bar{d}_m = \frac{\sum_0^\infty m_i d_i}{\sum_0^\infty m_i} = \frac{\sum_0^\infty h_i d_i}{\sum_0^\infty h_i}$$

or the number average particle diameter:

$$\bar{d}_n = \frac{\sum_0^\infty n_i d_i}{\sum_0^\infty n_i} = \frac{\sum_0^\infty h_i}{\sum_0^\infty h_i/d_i}$$

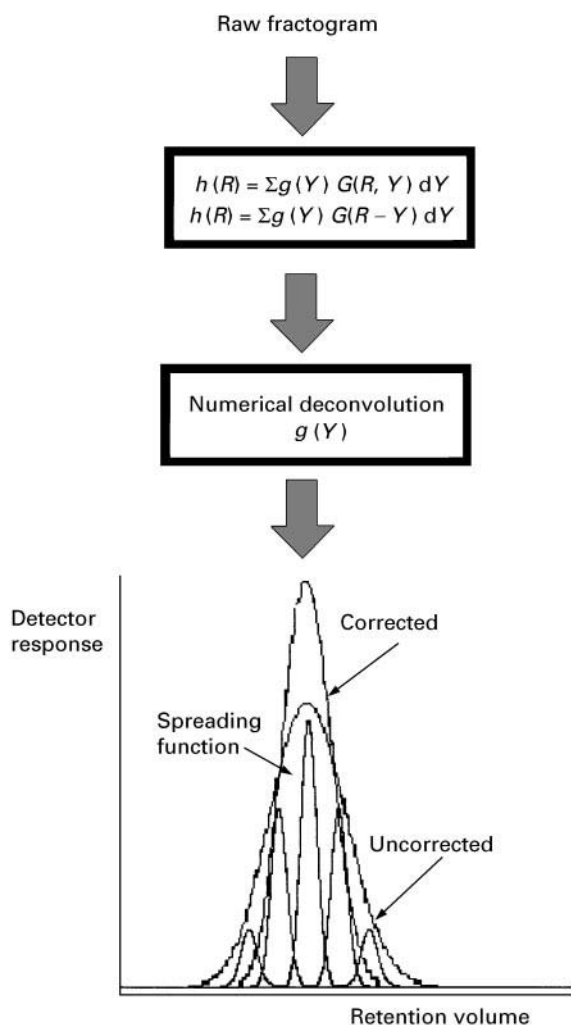

Figure 2 Schematic representation of a procedure for the treatment of a raw experimental fractogram to correct for zone broadening.

where h_i is the normalized detector response to the i th particle diameter. The polydispersity of the fractionated sample can be characterized, for example, by the index of polydispersity:

$$I = \frac{\bar{d}_m}{\bar{d}_n}$$

The above basic theory and data treatment can be applied independently of a particular FFF method or technique.

Instrumentation

Polarization FFF

In particle size separations by FFF, the nature of the applied field (physical or chemical forces) determines

each particular method or technique of polarization FFF and, consequently, the appropriate instrumentation. The most important polarization FFF methods at the present time are:

- sedimentation FFF
- flow FFF
- electric FFF
- thermal FFF

The basic experimental devices as well as specific instrumentation are described here for each particular FFF method or technique.

Independent of the method or technique, all FFF apparatuses are composed of a system of solvent delivery (reservoir, pump), injector sample (injection valve, syringe-septum, etc.), separation channel (different construction for each method), detector (refractive index detector, spectrophotometer, molar mass detector, etc.) and a data acquisition and treatment system (computer). With the exception of the FFF separation channel, all other components, and the system as a whole, are practically the same as a conventional liquid chromatography system.

Schematic representation of the separation channel for *sedimentation FFF* is shown in **Figure 3(A)**. The separation channel is coiled inside a centrifuge rotor. A delicate part of this separation unit is the rotating seal which must permit the flow-through of a carrier liquid and the connection to the injector at the entry to the channel proper and of a detector at the exit. However, this technical problem is solved and the rotors for sedimentation FFF are commercially available. On the other hand, a home-built solution is also possible providing that some technical skill is available.

If the particles to be separated are relatively large or dense and, consequently, the gravitational force is enough to generate the formation of sufficiently strong concentration gradients, the construction of the separation channel is much simpler, as shown in **Figure 3(B)**. In this case, the channel is composed of two sandwiched glass plates, one of them is provided with holes and capillaries for carrier liquid entry and exit and a thin foil in which the channel proper is cut. The whole channel must be positioned horizontally to avoid casual parasite convections which could cause the separation to deteriorate.

The channel for *flow FFF* is schematically demonstrated in **Figure 4(A)**. It is formed between two parallel, semipermeable membranes fixed on porous supports. The cross-flow of the carrier liquid is superposed perpendicularly to the flow of the carrier liquid in a longitudinal direction inside the channel. The cross-flow acts as an external field of hydrodynamic forces which generate a uniform flux of all particles.

Figure 3 Simplified schemes of the construction of the sedimentation FFF channels used in a centrifuge and in natural gravitational field. (A) Sedimentation FFF channel: (1) channel; (2) direction of the flow; (3) rotation; (4) flow inlet; (5) flow outlet. (B) Gravitational FFF channel: (1) channel walls; (2) foil spacer; (3) inlet and outlet.

The carrier liquid passes through the membranes but the separated particles should not, due to the conveniently chosen porosity of the membranes. The uniformity of the cross-flow is, however, not necessary to achieve high performance separation. If only one of the main channel walls is semi-permeable, a non-uniform hydrodynamic field is generated in such an asymmetrical flow FFF channel. The dependence of the separation resolution on particle size in such a channel is different compared with a channel equipped with two semi-permeable walls, but high performance particle size separation is also achieved.

A classical type of rectangular cross-section channel has sometimes been substituted with a circular cross-section capillary with an overpressure applied inside or by applying an external cross-flow in a more standard manner, as shown in Figure 4(B). The simplicity of the construction of such a 'channel' is the main advantage of this configuration. The theoretical description of the separation is complex, however, and, moreover, the probability of the formation of parasite flows degenerating the separation is higher.

The channel for *electric* FFF is usually formed by semipermeable membranes as in flow FFF (see Figure 5). The reason for such a solution is to decouple the separation channel proper from the electrode chambers and thus to avoid the contamination of the channel by products of electrolysis (gas bubbles). However, channels of simpler construction in which the metal or graphite electrodes form the channel walls and thus are not decoupled from the separation space have been constructed and work quite well under carefully chosen experimental conditions. The channel for *thermal* FFF is constructed in such a manner to allow a temperature difference between two metallic bar walls with highly polished surfaces. The walls are separated by a spacer in which the channel proper is cut. The upper bar is heated by using appropriate electrical cartridges and the lower bar is cooled by circulating water. Both bars should be equipped with several holes to accommodate the thermocouples for temperature control. Schematic representation of a channel for thermal FFF is shown in Figure 6. In some cases, when the temperature of

the heated wall is above the boiling point of the carrier liquid used, the channel must be sealed so as to operate under high-pressure conditions. The thickness of the channel can be as low as few micrometers which permits performing high-speed and high-resolution fractionations. The separation can be accomplished in just a few seconds.

Focusing FFF

Focusing FFF methods have been classified according to various combinations of the driving field forces and gradients:

- effective property gradient of the carrier liquid,
- cross-flow velocity gradient,
- lift forces,
- shear stress, and
- gradient of the non-homogeneous field action.

Figure 6 Construction of a channel for thermal FFF: (1) electric heating cartridge; (2) cooling liquid inlet and outlet; (3) foil spacer; (4) holes for thermocouples; (5) longitudinal flow inlet; (6) longitudinal flow outlet.

While this classification scheme is perfectly consistent with fundamental separation mechanisms and related driving forces, particular focusing FFF methods and techniques are more often called according to experimental procedure. The instrumentation will be described for each implemented focusing FFF method or technique.

The channels for sedimentation–flotation focusing field-flow fractionation (SFFFFF) or isoelectric focusing field-flow fractionation (IEFFFFF) are either of standard rectangular cross-section or of modulated cross-sectional permeability (for example, of trapezoidal or triangular cross-section), as shown in Figures 7(A) and (B). While the flow velocity profile in channels of rectangular cross-section are symmetrical (e.g. parabolic), the modulated cross-sectional permeability channels allow formation of flow velocity profiles which are not symmetrical. The advantage of these channels is that almost all zones focused symmetrically regarding the central longitudinal axis of the separation channel can be separated. If the flow velocity profile is symmetrical, the zones focused at the opposite sides regarding the central axis of the channel can be confused.

Both above-mentioned methods belong to the first category in which an effective property gradient of the carrier liquid represents the major driving force. The focusing in these cases can appear to be due to the effective property gradient of the carrier liquid in the direction across the channel combined with the primary or secondary transverse field.

It has been shown that the gradient of the effective property of the carrier liquid can be performed at the beginning of the channel. For example, the step density gradient can easily be formed by pumping the carrier liquids of various densities through several inlet capillaries into the channel. Such an arrangement can effectively be used for continuous preparative fractionation providing that the separation channel is also equipped with several outlet capillaries to continuously collect the fractions which are focused at different levels. Schematic representation of such a channel is shown in Figure 8.

The elutriation focusing field-flow fractionation (EFFFFF) method belongs to the category in which the focusing is due to the gradient of transversal flow velocity of the carrier liquid which opposes the action of the external field. The longitudinal flow of the carrier liquid is acting simultaneously. A trapezoidal cross-section as well as a rectangular cross-section channels can be used in this case. Schematic representation of such a channel for elutriation FFF is

Figure 7 (A) Schematic representation of a channel for sedimentation flotation focusing FFF in coupled electric and gravitational fields: (1) flow in; (2) flow out; (3) electrodes forming the channel walls; (4) spacer. (B) Schematic representation of a trapezoidal cross-section channel for isoelectric focusing FFF: (1) Pt anode; (2) Pt cathode; (3) anolyte; (4) catholyte; (5) ampholyte; (6) sample; (7) to detector; (8) trapezoidal cross-section channel; (9) membranes.

shown in **Figure 9**. The channel shown has a trapezoidal cross-section which causes formation not only of a convenient, axially asymmetrical flow velocity profile but, providing the volumetric transversal flow-in and flow-out are equal, a linear velocity gradient is established across the channel. In combination with different constant velocities of different size-separated particles the conditions for the focusing phenomenon to appear are established.

Figure 8 Continuous preparative channel for focusing FFF in preformed step density gradient: (1) gravitational field; (2) flow inlets; (3) flow outlets.

Very few experiments have been published on FFF exploiting the hydrodynamic lift forces at high carrier flow rates which, with the high shear gradient, result in the deformation of soft particles and their subsequent displacement and focusing. Similarly little has been published on FFF using a non-homogeneous high gradient external field. Although these methods can, in principle, use one of the types of channel described above for other focusing FFF methods, no experimental proof for this currently exists.

Conclusion

A large number and variety of homemade channels exist which confirms that in most cases, the construction of a channel is not extremely difficult.

Figure 9 Schematic representation of a channel for elutriation focusing FFF: (1) field force; (2) cross-flow; (3) longitudinal flow.

However, commercial FFF apparatus is increasingly available which could further stimulate interest in applying this high performance separation methodology in routine laboratory practice.

Introduction

The first separation of acids by gas chromatography (GC) coincides with the inception of GC itself. In 1952 James and Martin pioneered GC by demonstrating the separation of the C₁ to C₁₂ aliphatic acids on a stationary phase of silicone oil DC 550 containing stearic acid or H₃PO₄ and quantifying using a special titrimetric detector. Since then, the GC analysis of acids has been extended to a very wide variety of species and samples. To enable ready application of GC, the acids are usually converted to suitable volatile derivatives for resolution on efficient columns. As they are eluted they must be identified by an appropriate technique, the most definitive being mass spectrometry (MS). Various applications are presented in this article.

Derivatization

It was noted early on that separation of free acids is frequently hampered by their relatively low volatility, molecular association and, particularly, their adsorption on the stationary phase support with the resultant tailing, peak distortion and ghosting. Although special columns (FFAP, OV-351, SP-1000) have been developed since then for the separation of short and medium chain free (underivatized) aliphatic acids, the majority of carboxylic acids (especially those containing additional polar substituents) are insufficiently volatile for analysis by GC. Therefore, the carboxyl and other polar groups are usually converted to less polar derivatives to improve their chromatographic properties.

Carboxylic Acids

Both free and bound carboxyl groups are almost exclusively derivatized to volatile esters – predominantly silyl and methyl – by a variety of methods. These employ a number of silylation reagents, acid- and base-catalysed reactions, on-column pyrolysis,

diazomethane and other reagents. Each has its advantages, limitations and special applications.

Silyl esters Silylation is now one of the most extensively used techniques for esterifying free acids primarily because of its speed, convenience and the simultaneous derivatization of other polar functional groups containing an active hydrogen (–OH, –SH, –NH₂). The trimethylsilyl (TMS) group is the most commonly introduced substituent by the many silylating agents available, of which *N,O*-bis-(trimethylsilyl)trifluoroacetamide (BSTFA) is the most widely used. It reacts with all the common polar functionalities and yields volatile by-products that are usually eluted with the solvent. Even more volatile by-products are produced by substituted reagents, e.g. *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA), which are also more reactive toward the polar functional groups. Although all silylating reagents and their products are sensitive to moisture, considerably greater hydrolytic stability is exhibited by *t*-butyldimethylsilyl (TBDMS) derivatives that are best prepared with *N*-*t*-butyldimethylsilyl-*N*-methyltrifluoroacetamide (MTBSTFA), which can also serve as its own solvent. It yields excellent results with both volatile and nonvolatile carboxylic acids (Figure 1). A limitation of silylation is that bound acids such as lipids (triacylglycerols) are not converted and their derivatization to methyl (or other alkyl) esters is necessary.

Alkyl esters Methyl esters are most frequently prepared by acid-catalysed reactions with methanol. The principal advantage of this method is the concurrent esterification of free acids and the transesterification of bound ones. The most extensively used catalysts are BF₃, HCl and H₂SO₄, usually as 14%, 5% and 2% solutions, respectively. The reaction is fastest with BF₃, requiring the mixture to be boiled for 2 min for free acids and 30–60 min for lipids. With HCl and H₂SO₄ about twice the time is required. The higher concentration of BF₃ used compared to the other catalysts may be responsible not only for the faster reaction, but also for partial degradation of unsaturated acids and reported artefact formation. These problems can be reduced by prior saponification with methanolic KOH, followed by re-esterification of the free acids formed under mild conditions. Several official methods are based on this procedure.

Figure 1 Chromatogram of a mixture of carboxylic acids as the *t*-butyltrimethylsilyl derivatives. GC conditions: 30 m \times 0.32 mm i.d., DB-1 fused-silica capillary column initially at 60°C for 2 min, then programmed to 280°C at 4°C min⁻¹; 0.8 L sample, injected with split ratio of 15 : 1; both injector and detector temperatures at 300°C; nitrogen as the carrier gas at 0.9 mL min⁻¹. Substituting microwave irradiation for conventional heating may substantially reduce reaction times and lipid degradation. Thus, using the BF₃-methanol reagent, a reaction time of 30 s sufficed for the transesterification of most lipids to their fatty acid methyl esters (FAMES) with less oxidation of the unsaturated species.

Base-catalysed reactions are used extensively for the transesterification of lipids because they proceed faster than those in acid media without degradation of the unsaturated fatty acids. However, they do not esterify free fatty acids. The most commonly used reagents are methanolic solutions of NaOCH₃ or KOH. Transmethylation of lipids is usually complete in 5 min at room temperature.

Strong organic bases can be used similarly and possess the great advantage of forming salts which, unlike their inorganic analogues, can be pyrolysed to methyl esters at the high temperatures of a GC injection port. This permits simple one-step determination of both free and bound acids. The organic bases that have been recommended for such

pyrolytic conversions include (*m*-trifluoromethyl-phenyl)-trimethylammonium, trimethylphenylammonium and trimethylsulfonium hydroxides. The latter reagent requires the lowest pyrolysis temperature and yields innocuous by-products. It is simply added to the sample solution, mixed and injected.

Esterification of free acids with diazomethane proceeds rapidly in high yield under mild conditions, with minimal side reactions. Special microequipment, reagents and procedures have been developed that allow its relatively safe handling despite its toxic and explosive nature. Other reagents of interest include alkyl chloroformates that can esterify free acids even in the presence of a considerable amount of water (40%). Another reagent, dimethylformamide dimethylacetal, can be simply mixed with the sample of acid and injected into the GC; the reaction occurs in the hot injection port. Silver or potassium salts of acids can be converted to esters with methyl iodide or sulfate. Many other reactions have been reported.

Short chain acids are frequently derivatized to higher esters with butanol or isopropanol and acid

catalysts in order to mitigate losses due to volatility and substantial water solubility. Higher diazoalkanes may also be used if the methyl esters are too volatile.

Enantiomers of optically active carboxylic acids have been separated following acid-catalysed esterification with a chiral alcohol such as *S*(+)-2-butanol, *R*(-)-2-octanol, or (-)-methanol or transesterification with sodium menthylate. Diastereometric esters have also been prepared from optically active acids by reaction with *O*(-)-menthyl-*N,N*-diisopropylisourea.

The above silyl and alkyl esters are most commonly detected by a flame ionization detector (FID). Greater sensitivity, however, can be achieved by forming halogenated silyl esters, e.g. chloromethyldimethylsilyl, and monitoring with an electron-capture detector (ECD). Similarly, very small amounts of volatile acids may be detected via their pentafluorobenzyl (PFB) esters with an ECD. Special derivatives for this detector include the 2-chloroethyl and trichloroethyl esters.

Other derivatives The silyl and alkyl esters described are generally also suitable for detection by MS. However, special derivatives are necessary for unsaturated fatty acids to prevent double-bond migration during fragmentation. The most widely used derivatives are those of 3-hydroxymethylpyridine (picolinyl) and 4,4-dimethyloxazoline (DMOX). Picolinyl esters must be prepared from the acid but DMOX derivatives can be prepared even from their esters.

Amino Acids

For amino acids, derivatization is indispensable for analysis by GC since they all exist in the zwitterion form. Some also contain other polar functionalities, including hydroxyl, thiol and imino groups. The different reactivities of these groups greatly complicate their concurrent derivatization. Silylation offers the best approach for a single-step attachment of the same tag to all these functional groups.

The most successful attempt to generate a single product is by silylation with MTBSTFA to form TBDMS derivatives. Reaction conditions (heating at 150°C for 2.5 h) were developed for the reproducible derivatization of amino acids in high yield. TMS derivatives of the common amino acids, except arginine, can also be prepared with BSTFA under similar conditions.

An alternative method of derivatization of amino acids entails first esterification and then acylation to produce various *N*-acyl alkyl esters (Figure 2). The most widely used of these combinations is the

Figure 2 Separation of *N,O*-heptafluorobutyl amino acid isobutyl ester derivatives obtained from silkworm *t*-RNA after deacylation and analysed with FID. GC conditions: 25 m \times 0.4 mm i.d. capillary column coated with 5% Chromosorb R and 15% OV-101 SCOT column; carrier gas, hydrogen at a flow rate of 3 mL min⁻¹; make-up gas, nitrogen at a flow rate of 30 mL min⁻¹; hydrogen flow rate, 27 mL min⁻¹; air flow rate, 350 mL min⁻¹; temperatures: detector, 320°C; no inlet heater block; column, 80°C programmed at 4°C min⁻¹. Pulse interval, 15 μ s; attenuation, 2×10^2 ; sample size, 20 μ L. Peaks: 1, Alanine; 2, glycine; 3, valine; 4, threonine; 5, serine; 6, leucine; 7, isoleucine; 8, norleucine (l.s.); 9, proline; 10, methionine; 11, aspartic; 12, glutamic acid; 13, lysine; 14, tyrosine; 15, arginine. N-trifluoroacetyl-*n*-butyl ester (TAB) derivative. Esterification is performed by one of the methods described above and acylation by heating the dried product with trifluoroacetic anhydride. The selectivity of the NP detector can be exploited to monitor amino acids in the presence of interfering matrices, particularly lipids.

Enantiomeric resolution has been achieved with a chiral aliphatic alcohol and an achiral acylating agent such as *N*-trifluoroacetyl chloride. Alternatively, the amino group has been converted to diastereomeric amides, ureas, thioureas and isoindoles.

Resolution

Since many real samples are complex mixtures of acids (and other components), high efficiency

columns are essential for satisfactory resolution. This requirement has made packed columns effectively obsolete for such samples and use of capillary (or open tubular, OT) columns is becoming routine. The high efficiency of OT columns requires correspondingly less selectivity to gain the necessary separation. Therefore, relatively few different stationary phases in OT columns will adequately separate the majority of mixtures encountered.

Nonpolar stationary phases have the advantages of greater inertness, thermal stability and operation at lower temperatures. Since retention times increase with increasing polarities of the stationary phase and analyte, the least polar column affording the necessary resolution should be selected. Silyl derivatives are usually adequately separated on nonpolar polydimethylsiloxanes (e.g. DB-1, SE-30, OV-101); for greater selectivity somewhat more polar phases such as DB-5, SE-54, OV-17 or even OV-1701 may be used. On the other hand, stationary phases containing hydroxyl groups (such as the polyethylene glycols, PEGs) should be avoided because they react with silylation reagents.

Saturated and unsaturated FAMES are generally separated on more polar columns because they tend to cluster together on nonpolar phases, with the unsaturated ones preceding the saturated. On polar phases such as PEGs, the unsaturated are eluted after the saturated with minimal overlap of different chain lengths. This shift in retention behaviour is further enhanced on very polar stationary phases such as the cyanosilicones (CP-Sil-88, OV-275, DB-23) which are used for resolving *cis*, *trans* isomers and very complex mixtures.

Relatively nonpolar columns are used for the separation of diastereomeric esters formed from optically active carboxylic and amino acids. As an alternative approach, amino acid enantiomers have been separated as their alkyl *N*-perfluoroacyl derivatives on a chiral column, e.g. Chirasil-Val.

Identification

With conventional GC detectors, such as the FID and ECD, identification of the most commonly encountered acids is based on comparison of the retention times obtained with authentic standards. For unidentified acid peaks in general, retention index values or, for FAMES, equivalent chain lengths (ECL) from the literature may be helpful. The preferred solution is, however, MS detection in view of the more definitive structural information it provides. Especially for carboxylic acids, the usual data (e.g. molecular weights, fragmentation patterns, isotopic peak patterns) afforded by MS are supplemented by additional struc-

tural information, the most useful being the degree of unsaturation.

The presence of a double bond can be deduced from the molecular weight of an ester but its location cannot be ascertained due to migration during fragmentation. Hence, for reliable identification of positional isomers by GC-MS, two methods are employed: the on-site method of fixing the location of the double bond through its chemical modification, or the remote group method in which the carboxylic group is derivatized to a nitrogen-containing product which restricts double-bond migration. The remote group method is more convenient and versatile.

Chemical modification involves the addition of a reagent across the double bond of the acid ester to generate a product which gives diagnostic fragment ions. Dimethyl disulfide is a widely used reagent since it adds to a double bond in a single step at room temperature and enables identification of positional and geometrical isomers after separation on an appropriate column. But the picture is less clear with polyenoic acids, especially when the double bonds are in close proximity, and with acids containing other structural features such as cyclopropane rings. Diels-Alder reactions with cyclopentadiene derivatives can be applied similarly. The double-bond site may also be established by treating the unsaturated acid with OsO_4 and converting the resulting diol to the *bis*-TMS ethers for GC-MS analysis. Although this method is suitable for locating the double-bond sites of polyunsaturated acids, their fragmentation patterns are more complex and careful interpretation is necessary.

In derivatizing the carboxylic group, the picolinyl and DMOX compounds are the most commonly generated nitrogen-containing products. In the mass spectra of these derivatives, the saturated segments of the molecules are indicated by the regular separation of successive peak clusters by 14 amu (corresponding to the cleavage of a CH_2 group), whereas at double-bond sites the gap is only 12 amu. Furthermore, fragmentation on either side of the double bond gives two ions which are separated by 26 amu. In a branched acid derivative, the site of branching is shown by a similar gap of 28 amu.

Geometrical isomers and ring structures are more reliably identified by infrared (IR) spectrometry, which underscores the utility of GC-Fourier transform IR (FTIR)-MS in the structure elucidation of acids. However, the inherently lower sensitivity of IR requires larger sample sizes and columns with a higher load capacity.

Quantitative analysis of acids by GC-MS is carried out most sensitively by selected ion monitoring (SIM) employing an isotopically labelled analogue or a

derivative of a structurally similar acid as internal standard. The desired sensitivity of detection is a critical factor in the choice of the derivative. For increased sensitivity ion currents must be intensified by reducing fragmentation. Hence, TBDMS derivatives are preferred to those of TMS. Moreover, TBDMS derivatizes the amino acids arginine and glutamine, whereas TMS fails to do this. (However, the preferred method for quantification of amino acids involves the butyl perfluoroacyl derivatives.) Fragmentation may also be reduced by increasing molecular stability via cyclic derivatives, as illustrated by quinoxalinol compounds utilized in the GC-MS analysis of 2-oxo-acids. An excellent method of augmenting sensitivity is performing negative ion mass spectrometry via derivatives (e.g. *p*-nitrobenzyl, pentafluorobenzyl) with high electron affinity.

These methods have allowed the determination of a variety of acids by GC-MS at pg levels. Even mixtures of acids can be analysed quantitatively by monitoring several characteristic ions. Programmable SIM, which optimizes the selectivity at various points in a chromatogram and the desired sensitivity of analysis, has been invaluable in this regard.

Applications

Examples of GC analysis of acids in real-world samples are so numerous and diverse as to permit only representative cases from more significant fields to be cited.

Carboxylic acids present at abnormal levels in plasma and urine may indicate various metabolic disorders. Hence, their monitoring is vital for diagnostic purposes. GC has simplified such analysis by expediting the separation and determination of very low concentrations of acids present in these complex matrices (**Figure 3**). For example, C₂₇ and C₂₉ bile acid levels provide the basis for a screening test for a genetic condition characterized by peroxisomal dysfunction syndrome and are measured by GC-MS as methyl-silyl derivatives. Elevated levels of certain acylcarnitines may signify a potentially lethal condition caused by the deficiency of an enzyme which is essential for β -oxidation of fatty acids. Their quantification by GC-MS has been achieved by the ready conversion to volatile acyloxylactones. Metabolic products of amino acids whose presence in urine at unusually high levels may be symptomatic of

Figure 3 Chromatogram of a 3-hydroxy-dicarboxylic aciduria. GC conditions: 30 m \times 0.32 mm i.d. column coated with OV-1701; temperature-programmed from 70 to 270°C at a rate of 5°C min⁻¹. Detector: FID. Some important peaks are indicated: 1, lactic di TMS; 2, oxalic di TMS; 3, 3-hydroxy-propionic di TMS; 4, 3-hydroxybutyric di TMS; 5, 3-hydroxy-isobutyric di TMS; 6, 2-methyl-3-hydroxybutyric di TMS; 7, 3-hydroxy-isovaleric di TMS; 8, internal standard; 9, 3-hydroxy-adipic lactone mono TMS; 10, adipic di TMS; 11, hexenedioic di TMS; 12, triglycine mon TMS; 13, 4-hydroxy-phenylacetic di TMS; 14, octenedioic di TMS; 15, 3-hydroxy-adipic tri TMS; 16, suberic di TMS; 17, 3-keto-adipic enol tri TMS; 18, aconitic tri TMS; 19, citric tetra TMS; 20, hippuric mono TMS; 21, decenedioic di TMS; 22, 3-hydroxy-octenedioic tri TMS; 23, 3-hydroxy suberic tri TMS; 24, sebacic di TMS; 25, 4-hydroxy-phenyllactic tri TMS; 27, 3-hydroxy-decenedioic tri TMS; 28, 4-hydroxy-phenylpyruvic enol tri TMS; 29, 3-hydroxy-sebacic tri TMS; 31, 3-hydroxy-dodecadienedioic tri TMS; 32, 3-hydroxy-dodecenedioic tri TMS; 33, 3-hydroxydodecenedioic tri TMS; 34, 3-hydroxy-dodecanedioic tri TMS; 37, 3-hydroxy-tetradecadienedioic tri TMS; 38, 39, 3-hydroxy-tetradecenedioic tri TMS; 40, 3-hydroxy-tetradecanedioic tri TMS; Ph = phosphoric tri TMS. (Reproduced with permission from Lefevre MF, Verhaeghe BJ, Declerk DH *et al.* (1989) Metabolic profiling of urinary organic acids by single and multicolumn capillary gas chromatography. *Journal of Chromatographic Science* 27: 23.

metabolic disorders, e.g. hydroxyproline in collagen metabolism, and γ -carboxyglutamate in blood coagulation and bone metabolism. These compounds are converted to *N*-isobutyloxycarbonyl methyl derivatives prior to measurement.

Prostaglandins, which are indicators of several diseases, are a class of acidic biomolecules whose measurement in biomatrices still presents a formidable analytical challenge. They are present in urine at concentrations as low as few pg mL^{-1} and require the quantification of several structurally closely related compounds. The difficulties are further compounded by their extreme sensitivity to acids, bases and oxygen. The determination of prostaglandin E_2 has been achieved by negative ion chemical ionization (NICI)-GC-MS following methylation and derivatization of other functionalities. There are several methods reported for the determination of other prostaglandins by isotope dilution GC-MS. GC-MS has been of immense utility in elucidating the role of γ -aminobutyric acid as a neurotransmitter via its ^{15}N -labelled derivative. Catecholamines and their acidic metabolites such as homovanillic, vandilomandelic, 5-hydroxyindole-3-acetic and phenylacetic acids, are implicated as etiological factors in affective disorders. They have been determined by NICI-GC-MS via acetyl-PFB derivatives and by isotope dilution GC-MS. In clinical research, GC-MS has proved invaluable for pharmacokinetic studies of therapeutic

drugs with acidic functionalities. Such studies have been performed on methylphenidate, which is used in the treatment of children suffering from hyperkinesia, and on the butyl ester-trifluoroacetyl derivative of isotopically labelled histidine in investigations of the hereditary metabolic disorder histidinaemia. Another application is the analysis of the anti-inflammatory drug biphenylacetic acid in urine and synovial fluid by NICI-GC-MS-MS via its PFB ester. Some therapeutic drugs can lead to a build-up of toxic metabolites that must be monitored. This is exemplified by GC-MS analysis of patients' urine and plasma for 2-*n*-propyl-4-pentenoic acid, which is a product of the antiepileptic drug valproic acid.

In analytical microbiology, GC of fatty acids provides a basis for microbial chemotaxonomy and a means of identifying genus, species and even strains of microorganisms (Figure 4). The compounds profiled may be the nonvolatile C_{10} – C_{20} fatty acids present in cell membranes or the volatile acids which accumulate in the headspace. The extraction of the nonvolatile fatty acids and their derivatization to alkyl esters have been simplified by commercially available automated systems. Fatty acid profiles have permitted identification of pathogenic bacteria and even strains of yeast.

The realization that the enantiomers of a chiral compound may exhibit different bioactivities has prompted pharmaceutical and other industries to

Figure 4 Reconstructed chromatogram of fatty acid methyl esters from the unicellular alga *Tetraselmis suecica* obtained by GC-MS. Chromatographic conditions: 50 m \times 0.20 mm i.d. methylsiloxane fused capillary column; column temperature, initially at 40°C for 1 min, increased to 120°C at 30°C min^{-1} and then to 310°C at 4°C min^{-1} ; helium carrier gas. (Reproduced with permission from Volkman JK, Jeffrey SW, Nichols PD *et al.* (1989) Fatty acid and lipid composition of ten species of microalgae used in mariculture. *Journal of Experimental Marine Biology and Ecology* 128: 219.

ascertain the optical purity of products and the metabolic fate of each enantiomer. As a result, industries and regulatory bodies have evinced interest in reliable methods for resolving optically active compounds. In the particular case of chiral acids, GC has proved invaluable. This is clearly illustrated by the separation of the optical isomers of the common drug ibuprofen via diastereoisomeric esters, and by a group of anti-inflammatory drugs, arylpropionic acids, which are routinely monitored in biological fluids as their *R*(-)/*S*(+)-amphetamine derivatives.

The differentiation between biogenic and non-biological urinary carboxylic acids is vital in the forensic sciences to establish the use of illicit drugs. Cannabis is the most widely used illicit drug in the world. 11-Nor- Δ -9-tetrahydrocannabinol acid (THCA) is found in urine specimens of cannabis users at few ng mL^{-1} levels as a major metabolite of tetrahydrocannabinol. THCA may be detected in urine 4–6 days after use of marijuana and even up to a month in chronic users: its determination by GC, principally as the TMS derivative, has been the focus of much research. Benzoylecgonine, which is a car-

boxylic acid produced by de-esterification of cocaine at physiological pH and temperature, and ecgonine methyl ester are the major metabolites that appear in the urine of cocaine users. Both are analysed by either GC-ECD or GC-FID, after converting the acid to the TMS derivative.

Toxic haloacids are environmentally significant and may be present in drinking water and other beverages. They are monitored by GC-MS or GC-ECD as the methyl esters. Low concentrations of pesticide and herbicide residues contaminating fruits and vegetables present another health hazard, e.g. residues of the fungicidal metal salts of alkylene-*bis*-dithiocarbamic acids. These fungicides are first converted to CS_2 for analysis by headspace GC. Traces of some widely used acidic herbicides, such as chlorinated phenoxy-carboxylic acids, are quantified in food samples by GC-MS as their methyl esters.

Carboxylic acids and derivatives are important flavour and aroma constituents of foods (Figure 5) and beverages. Volatile fatty acids that are present at low concentrations also contribute to organoleptic characteristics and can be determined by headspace GC in

Figure 5 Gas chromatogram of free fatty acids (FFAs) from cheese spiked with an FFA reference mixture and short chain FFA (2:0, 3:0, 2- CH_3 -3:0, 5:0, 3- CH_3 -4:0 and 7:0). Chromatographic conditions: 25 m \times 0.32 mm i.d. fused silica capillary column coated with FFAP-CB; oven temperature-programmed to increase from 65 to 240°C at a rate of 10°C min^{-1} ; FID detector; helium carrier gas at a flow rate of 2 mL min^{-1} . Peaks: 1, C2; 2, C3; 3, 2- CH_3 -C3; 4, C4; 5, 3- CH_3 -C4; 6, C5; 7, C6; 8, C7; 9, C8; 10, C9; 11, C10; 12, C10:1; 13, C11; 14, C12:0; 15, C12:1; 16, C13-iso; 17, C13:0; 18, C14-iso; 19, C14:0; 20, C14:1 + C15-iso; 21, C15-anteiso; 22, C15:0; 23, C15:1; 24, C16-iso; 25, C16:0; 26, C16:1; 27, C17-iso; 28, C17-anteiso; 29, C17:0; 30, C17:1; 31, C18-iso; 32, C18:0; 33, C18:1; 34, C18:2; 35, C18:2; 36, C19:0; 37, C18:3; 38, C18:2 conjugated; 39, C20:0; 40, C20:1. underivatized form. Fatty acids containing unusual structural features, such as cyclopropane rings or epoxy groups, are constituents of some edible vegetable oils and are suspected of being health hazards. Hence they have been analysed in foods by capillary GC as FAMES. Such studies have provided a basis for identifying components in blends of vegetable oils with potential application to detecting adulteration. Similar studies have been carried out to determine brominated acid constituents in vegetable oils that are added to disperse flavouring constituents in citrus-based beverages. Clinical and epidemiological findings of the beneficial effects of fish oils have led to GC methods, effected on polar capillary columns, for determining ω -fatty acids such as eicosapentaenoic and docosahexaenoic acids in foods. *Trans* isomers of fatty acids have a possible link with cardiovascular diseases. Hence the occurrence of *trans* isomers in relatively large concentrations in margarines, shortenings and similar food products has stimulated development of methods for resolving geometrical isomers. The solution of this problem is very difficult by GC alone and has required the use of very long capillary columns and preliminary separation steps. It may be cited as an existing challenge to GC in the analysis of acids.

Conclusion

GC continues to be the method of choice for the analysis of acids because of its speed, efficiency and sensitivity. However, very complex mixtures still pose serious challenges. Future developments may entail use of shorter, narrower capillary columns for greater speed and, in conjunction with routine MS

detection, for more definitive identification. Automation of sample preparation, perhaps in conjunction with microwave irradiation in lieu of conventional heating, will shorten derivatization times, relieve the tedium of manual manipulations and reduce total analysis times.

Introduction

The determination of carboxylic acids is important in many areas of application, including environmental samples, foods and beverages, and pharmaceutical and biological materials. The modes of high performance liquid chromatography (HPLC) used most frequently in the separation of carboxylic acids are ion suppression chromatography, reversed-phase ion interaction chromatography, ion exclusion chromatography and ion exchange chromatography.

In ion suppression chromatography, a buffer of appropriate pH is added to the mobile phase in order to suppress the ionization of the carboxylic acids so that they can be retained on nonpolar stationary phases and eluted in order of increasing hydrophobicity. Ion interaction (or ion pair) chromatography has been used for the separation of carboxylic acids under isocratic or gradient conditions and involves the complete ionization of the solute and the addition to the mobile phase of an ion interaction reagent (IIR), consisting of lipophilic ions of opposite charge to the solute. Ion exclusion chromatography (i.e. the separation of partially ionized carboxylic acids on a cation exchange stationary phase using amperometry, coulometry, ultra-

violet, refractive index and both suppressed and nonsuppressed conductivity detection) is the most commonly used mode of liquid chromatography for the separation of carboxylic acids. Finally, anion exchange chromatography can be used for the separation of carboxylic acids, after conversion of these species to anions. Detection is usually achieved by suppressed or nonsuppressed conductivity or by indirect photometry.

Ion Suppression Chromatography

Background

Ion suppression chromatography is a technique for the separation of ionizable solutes which functions by suppressing the ionization of these solutes, thus increasing their retention on nonpolar stationary phases. In the separation of carboxylic acids, an acidic buffer is added to the mobile phase to suppress the ionization of the solutes, which are then separated on nonpolar polymeric or silica-based (usually C_{18}) stationary phases.

This method is only applicable to those acids for which the ionization can be suppressed using buffers having pH values in the range 3–8, since the C_{18} stationary phases are unstable outside this pH range. However, these restrictions do not apply to the use of polymeric stationary phases, which can be used for the separation of a wider variety of solutes. The mobile phase is usually an acidic buffer of the appropriate pH. Commonly used buffers include phosphoric acid, sodium or potassium phosphate, sodium hydrogen sulfate, acetic acid and citric acid. Organic modifiers such as methanol or acetonitrile can also be added to the mobile phase to improve the separation.

Manipulation of Retention of Acids in Ion Suppression Chromatography

Solute retention results from solvophobic effects occurring between the mobile phase, the stationary phase and the solutes. For the separation of monocarboxylic acids, the pH of the mobile phase influences the retention behaviour according to the following equation:

$$k' = \frac{k_0 - k_{-1} \frac{K_a}{[H^+]}}{1 + \frac{K_a}{[H^+]}} \quad [1]$$

where k_0 is the retention factor of the undissociated acid, k_{-1} is the retention factor of the conjugate base, and K_a is the acid dissociation constant in the mobile phase. This retention behaviour is illustrated in **Figure 1**, which shows the retention factor of a weak acid versus $(pH - pK_a)$. The curve is sigmoidal in shape

Figure 1 Plot of the retention factor of a weak monoprotic acid vs. $(pH - pK_a)$.

and the inflection point is located at the point where the pH of the mobile phase is equal to the pK_a of the solute in the mobile phase. At pH values substantially less than its pK_a value, the acid is present in its neutral form and has a large retention factor. Further decreases in mobile-phase pH show no effect on retention factor, since there will be no further change in the ionization of the acid. Conversely, mobile-phase pH values substantially greater than the pK_a value will result in complete ionization of the solute, leading to a small retention factor. At intermediate pHs, the solute charge, and hence its retention, will be dependent on the particular pH used and its proximity to the pK_a value.

In the case of dicarboxylic acids, the shape of the curve is largely determined by the difference between the two pK_a values. When pK_{a1} and pK_{a2} are very close, sigmoidal curves are obtained and the behaviour of dicarboxylic acids is almost the same as that of monocarboxylic acids. When the two pK_a values are well separated, the curve is a composite of two sigmoidal curves.

Both the ionic strength and organic modifier content of the mobile phase may be varied in order to manipulate retention in ion suppression chromatography. Increasing the ionic strength of the mobile phase causes an apparent increase in the dissociations, leading to a decrease in the retention factor.

This effect is more pronounced in nonaqueous media. In the approximate range of ionic strengths from 0 to 0.5 mol L^{-1} , the higher the ionic strength of the mobile phase, the greater the increase in ΔpK_a . The addition of organic modifiers influences retention behaviour in two ways. Firstly, increasing the organic modifier content of the mobile phase decreases the retention factor, as is generally the case in reversed-phase liquid chromatography. However, the apparent pK_a of the solute increases as organic modifier is added to the mobile phase, leading to an increase in the degree of ionization of the solute and therefore reduced retention.

Applications

The utility of ion suppression on polymeric stationary phases may be appreciated by considering the separation of the homologous series of aliphatic carboxylic acids. Neither ion exchange nor ion exclusion chromatography yields a complete separation of these species. However, ion suppression coupled with gradient elution and conductivity detection enables the separation of butyric through to stearic acid, as illustrated in **Figure 2**. The gradient used involved an increase in the percentage of organic modifier in the mobile phase and a decrease in mobile-phase pH. Carboxylic acids more hydrophilic than butyric acid are eluted in a single peak at the column void volume.

Ion Interaction Chromatography

Background

Ion interaction chromatography involves the addition of an ion interaction reagent (IIR) to the mobile

phase. The IIR is usually a lipophilic ion of opposite charge to the analyte ions. In the case of the separation of carboxylic acids, cationic IIRs such as tetraalkylammonium salts are used.

The mechanism of ion interaction chromatography is considered to begin with the establishment of a dynamic equilibrium between IIR in the mobile phase and IIR adsorbed onto the stationary phase:

where the subscripts M and S refer to the mobile and stationary phases. This results in the formation of an electrical double layer at the stationary phase surface. The adsorbed IIR ions constitute a primary layer of charge, to which is attracted a diffuse, secondary layer of oppositely charged ions. This secondary layer of charge consists chiefly of the counter-ions of the IIR. The double layer is shown schematically in **Figure 3A**. A solute anion can compete for a position in the secondary charged layer, from which it will tend to move into the primary layer as a result of electrostatic attraction and, if applicable, reversed-phase solvophobic effects. The presence of such a solute anion in the primary layer causes a decrease in the total charge of this layer, so to maintain charge balance a further IIR ion must enter the primary layer. The result is that solute retention involves the adsorption of a solute anion accompanied by the adsorption of an IIR ion, shown schematically in **Figure 3B**.

Typical stationary phases used in ion interaction chromatography include neutral poly(styrene-divinylbenzene) (PS-DVB) polymers and bonded silica materials with C_{18} , C_8 , phenyl and cyanopropyl groups as the chemically bound functionality. The

Figure 2 Gradient elution ion suppression chromatography of carboxylic acids, obtained on a polymeric reversed-phase column. A Dionex MPIC-NS1 column was used with a gradient of 100% mobile phase A ($t = 0$) to 100% mobile phase B ($t = 20$ min), with maintenance of mobile phase B after this time. Mobile phase A was 24% acetonitrile and 6% methanol in 0.03 mmol L^{-1} HCl; mobile phase B was 60% acetonitrile and 24% methanol in 0.05 mmol L^{-1} HCl with detection by suppressed conductivity. The baseline conductance for a blank gradient has been subtracted in the chromatogram shown. Figure 3 Schematic illustration of the ion interaction model for the retention of anionic solutes in the presence of a lipophilic cationic IIR. The solute and the IIR are labelled on the diagram. The long hatched boxes represent the lipophilic stationary phase, the black circles with negative charges represent the counter-anion of the IIR, whilst the white circles with positive charges represent the counter-cation of the solute. (Reprinted with permission from Haddad and Jackson, 1990.)

choice between stationary phases is usually based on considerations such as chromatographic efficiency, pH stability and particle size. However, the elution position of certain ions can differ between different stationary phases. Further factors to be considered in the selection of a stationary phase for ion interaction chromatography are specific interactions existing between the stationary phase and either the IIR or the solutes, and the role of residual silanol groups on silica-based stationary phases.

The most important component of the mobile phase in ion interaction chromatography is the IIR itself. The requirements of the IIR are that its charge is unaffected by mobile-phase pH, it has suitable lipophilicity to permit adsorption onto nonpolar stationary phases, and it is compatible with other mobile-phase components and the desired detection system.

In the separation of carboxylic acids by dynamic coating ion interaction chromatography, moderately hydrophobic strong base cations, such as tetrabutylammonium ions, are used as the IIR. The IIR is present at a constant, specified concentration in the mobile phase in order to maintain a desired concentration of IIR on the stationary phase. The lipophilicity of the IIR governs the degree to which it is adsorbed onto the stationary phase, which in turn governs the effective ion exchange capacity of the column and hence the retention times of solute ions.

An alternative to the above method is permanent coating ion interaction chromatography, where a very lipophilic IIR is used initially to equilibrate the stationary phase and is then removed from the mobile phase in the separation step. The coating persists for long periods of subsequent use. Permanent coating of the column is achieved by passing a solution of the

IIR (approximately 10^{-3} mol L $^{-1}$) in dilute (5%) methanol or acetonitrile through the column for about 20 min. The purpose of the organic solvent is to wet the surface of the lipophilic stationary phase in order to improve binding of the IIR.

The counter-ion of the IIR is important in dynamic coating ion interaction chromatography of anionic solutes. This counter-ion usually acts as an ion exchange competing anion and is responsible for the elution (and in many cases also the detection) of the solute anions. The nature of the counter-ion determines the type of separation which is required and the mode of detection applicable.

Manipulation of Retention of Acids in Ion Interaction Chromatography

The parameters which affect the adsorption of the IIR onto the stationary phase and hence the retention of solutes include the nature of the stationary phase, the lipophilicity of the IIR, the concentration of the IIR in the mobile phase, the ionic strength of the mobile phase, the nature and concentration of any competing ion added to the mobile phase, and the mobile-phase pH.

The first four of these factors will determine the surface concentration of the IIR on the stationary phase, and hence the surface charge density and the effective ion exchange capacity. The higher the surface concentration of IIR, the greater the solute retention. Thus, retention times will increase as the lipophilicity of the IIR is increased and as the percentage of modifier in the mobile phase is decreased. Solute retention generally increases with the concentration of IIR in the mobile phase, but there is a threshold concentration above which solute retention decreases with further increase in the concentration of IIR. The stationary phase becomes saturated with IIR and any further addition to the mobile phase results in decreased retention because of the increased concentration of the IIR counter-ion.

The nature and concentration of any competing ion added to the mobile phase will determine the retention times and elution order for solute ions. Increases in the concentration of the mobile phase competing ion will result in decreased solute retention, in the same manner as observed for ion exchange separations. Finally, the mobile phase pH may influence the charges on the competing ion and the solutes. An example of this effect is the influence of pH in an ion interaction chromatographic system using tetrabutylammonium as the IIR and phthalate as the competing anion. Increases in mobile-phase pH over the range 4.0–6.0 cause a decrease in the solute retention as a result of increased ionization of phthalate,

leading to the formation of a strong, divalent competing anion.

Applications

Carboxylic acids are usually separated by ion interaction chromatography using a reversed-phase column with quaternary ammonium salts as the IIR and water-methanol or water-acetonitrile as the mobile phase. The more lipophilic the quaternary ammonium ion, the more the acid is retained on non-polar stationary phases. Such separation systems have been used for the determination of ascorbic acid in fruits and vegetables, as well as carboxylic acids in beverages such as wine, beer and fruit juices.

Gradient elution ion interaction chromatography is also possible. The concentration of the organic modifier or the pH of the mobile phase may be varied to optimize the separation. **Figure 4** shows an example of the separation of carboxylic acids on a reversed-phase column by gradient elution using tetrabutylammonium hydroxide as the ion interaction reagent.

Ion Exclusion Chromatography

Background

Ion exclusion chromatography was first introduced by Wheaton and Bauman in 1953. In this mode of chromatography, the negatively charged, partially dissociated carboxylic acids are separated on cation exchange resins comprising silica or a polymer with chemically bound anionic sulfonate or carboxylate functional groups. This is the opposite situation to that occurring in normal ion exchange chromatography.

The chromatographic system consists of three phases: the mobile phase, the resin phase and an occluded liquid phase. The mobile phase passes through the interstitial volume existing between the beads of the ion-exchange resin. An occluded liquid phase is formed by mobile phase that becomes trapped within the pores of the resin phase. This trapped liquid acts as the stationary phase of the system. The resin phase is the solid resin network and functionalized groups, which can be considered to be a semipermeable ion-exchange membrane separating the flowing mobile phase from the stationary occluded liquid inside the resin. The three phases are illustrated schematically in **Figure 5**.

Fully ionized species (A^-) are completely excluded from the interior of the resin due to electrostatic repulsion by the fixed anionic functional groups, in accordance with the Donnan exclusion effect. Therefore, these species are not retained and are eluted at

Figure 4 Ion interaction chromatography of carboxylic acids on a LiChrosorb RP-8 column with a mobile phase of aqueous tetrabutylammonium hydroxide (1 g L^{-1}) and methanol using gradient elution. Detection was at 254 nm. Carboxylic acids are: 1, ascorbic; 2, oxalic; 3, pyruvic; 4, fumaric; 5, maleic. Chromatogram courtesy of Alltech Chromatography Catalog (1997) 610.

the column void volume. Partially ionized species like weak carboxylic acids ($pK_a = 2.5\text{--}6.5$) permeate selectively into the stationary phase (the occluded liquid trapped within the pores of the resin), resulting in some retention of these species, which are then eluted some time later than the fully ionized solutes.

Ion exclusion chromatography was first performed on large particle size, high capacity, fully functionalized PS-DVB polymers. However, separations have also been performed on polymethacrylate copolymer resins, as well as on silica. Separations of carboxylic acids by modern ion exclusion chromatography are usually carried out on a cation exchange column containing sulfonated functional groups ($-\text{SO}_3^-$) or mixed sulfonate and carboxylate functional groups, with the resin most commonly being used in the hydrogen form.

Ion exclusion columns are usually quite large because most sample species are eluted with retention volumes intermediate between the interstitial volume (V_0) and $V_0 + V_i$, where V_i is the occluded (or intraparticle) liquid volume. Large columns contain more

Figure 5 Schematic representation of the ion exclusion mechanism, showing the retention of a weak acid (HA) in the occluded liquid phase and the exclusion of the acid anion (A^-).

resin, thus increasing the amount of occluded liquid and hence also the capacity of the stationary phase. A typical column would be 30 cm in length, with an internal diameter of 7 mm or more.

The mobile phases used in ion exclusion chromatography are often very simple in composition. Most of the early work was performed using water as the mobile phase. However, water has limitations as stronger acids or bases show too great a degree of ionization to be retained and for weaker acids such as carboxylic acids, the separation is slow and the peaks are unsymmetrical.

In modern ion exclusion chromatography it is common to use dilute solutions of strong mineral acids for the elution of carboxylic acids. The dilute mineral acid solution suppresses the ionization of the acids so that they can partition into the occluded liquid phase, resulting in longer retention times and better separation between the stronger carboxylic acids. The choice of acid used in the mobile phase is usually determined by the form of detection being used. Sulfonic acids are used for conductivity detection without suppression since mineral acids have a high background conductance. Sulfuric acid is often used with ultraviolet detection and hydrochloric acid is used with conductivity detection after the mobile phase has been passed through a suitable suppressor. Weak acids such as benzoic acid, phosphoric acid, salicylic acid and carbonic acids have also been used as mobile phases in ion exclusion chromatography when conductivity detection is utilized.

Manipulation of Retention of Acids in Ion Exclusion Chromatography

The dominating factor which determines retention is the degree to which the acid is ionized. Separation is based on the electrostatic repulsion between the

solute ions and fixed functional groups of the resin. Therefore, ionic species are excluded from the stationary phase while partially ionized or uncharged species partition between the mobile phase and the occluded liquid within the resin pores. Assuming this is the only mechanism, the solute retention time, t_R , is given by:

$$t_R = t_0 + D_A t_i \quad [3]$$

where t_0 is the time taken for the interstitial volume of mobile phase (i.e. the volume of mobile phase flowing between the resin beads) to be eluted, t_i is the time taken for the volume of occluded liquid inside the pores of the resin to be eluted, and D_A is the distribution constant for the solute between the interstitial mobile phase and the occluded liquid. The value of D_A is dependent on the degree of ionization of the solute.

If a solute cannot enter the stationary phase because it is fully ionized (ion exclusion), $D_A = 0$. Therefore, the retention time of fully ionized solutes is equal to t_0 , whilst for an uncharged solute which is free to enter the stationary phase, $D_A = 1$, and its retention time is equal to t_i . Thus, in the separation of carboxylic acids, the retention times of the acids depend on their first dissociation constants (pK_a). Since the fraction of the ionized solute molecules increases with increasing pH, an increase in the mobile phase pH will reduce the retention time.

The retention times of monocarboxylic acids larger than acetic acid, and dicarboxylic acids larger than succinic acid, show an increase with increasing carbon number, even for solutes with similar pK_a values. This increased retention can be attributed to hydrophobic adsorption of the solutes on to the neutral, unfunctionalized regions of the polymeric resin, in a manner similar to that observed in reversed-phase

HPLC. Hydrophobic adsorption effects can be expected to increase in magnitude as the alkyl chain length of the solute is increased, leading to larger retention times. In the case of aromatic acids, the interaction of π -electrons of the benzene ring of the acid with those of the ion exchanger (such as styrene-divinylbenzene packing materials) leads to much higher retention times than expected from their pK_a values. The existence of hydrophobic adsorption effects creates the possibility for manipulation of solute retention by adding typical reversed-phase organic modifiers, such as methanol or acetonitrile, to the mobile phase.

Ion exclusion chromatography is usually carried out on a high-capacity sulfonated PS-DVB resin in the H^+ form. However, recently work has also been carried out using a polymethacrylate resin in the H^+ form with carboxylate functional groups, bare silica (where the silanol group on the surface of the silica acts as the anionic functional group) and also on silica-based cation exchangers functionalized with alkylsulfonic acid or phenylsulfonic acid groups. Since silica gel is chemically stable and inert to organic solvents, silica-based cation exchangers offer the advantage that high concentrations of organic modifiers can be used. Also, aromatic acids which adsorb strongly on to PS-DVB resin due to π -electron interactions between the aromatic ring and the solid resin network are eluted earlier when using a silica gel column.

Other factors which play a part in the retention process of carboxylic acids in ion exclusion chromatography include the addition of other mobile phase modifiers such as polyols, sugars and inclusion compounds (e.g. β -cyclodextrin), as well as resin characteristics such as the pore size, the degree of cross-linking, the ion exchange capacity and the ionic form of the resin.

Applications

The separation of carboxylic acids is the most common application of ion exclusion chromatography. When coupled with spectrophotometric detection at low wavelength (e.g. 210 nm), ion exclusion chromatography yields excellent separations and relatively clean chromatograms for a wide variety of complex sample matrices, such as urine, plasma, foods and beverages and pharmaceuticals. Figure 6 shows a chromatogram for a urine sample, without sample pretreatment. Ion exclusion chromatography has also found increasing use for the determination of anions of weak inorganic acids. It is especially attractive as an adjunct to ion exchange chromatography since the selectivities obtained by these two techniques are quite different. Solutes such as

fluoride, carbonate, cyanide, borate and sulfite have been determined using this approach. Interference from strongly ionized species is minimal because these solutes are unretained and appear at the column void volume. Ion exclusion chromatography can therefore readily separate weakly ionized solutes in samples containing high concentrations of ionic species, e.g. sea water and oil reservoir brines.

Ion Exchange Chromatography

Background

Ion exchange chromatography of carboxylic acids can be performed using an anion exchange stationary phase. The capacity of this anion exchanger is important since the capacity needs to be sufficiently high to separate carboxylic acids of similar charge, but low enough for the ionic strength of the mobile phase to permit the use of conductivity detection. The development of new high-efficiency, low- and medium-capacity columns combined with a new generation of micromembrane suppressors capable of handling concentrated mobile phases has made the determination of carboxylic acids by anion exchange chromatography a practical proposition.

One disadvantage of anion exchange chromatography is that groups of mono-, di- and tricarboxylic acids must be analysed separately. However, the use of gradient elution (water, sodium hydroxide and methanol) has made it possible to separate these compounds in a single run, as well as simultaneously separating inorganic anions (Figure 7).

Ion exchange chromatography of carboxylic acids has been performed on anion exchange resins in the hydroxyl, carbonate, sulfate, chloride, nitrate, formate, acetate or borate form. The mobile phase usually consists of an alkaline solution such as sodium hydroxide or sodium carbonate and sodium hydrogen carbonate, with detection achieved using a suppressor column and conductivity. Solutes are usually low-molecular-weight, saturated or unsaturated acids and hydroxy acids. Factors which affect retention include molecular dimensions, pK_a and specific adsorption of organic acid molecules on the organic matrix of the ion exchanger.

Manipulation of Retention of Acids in Ion Exchange Chromatography

Apart from the usual electrostatic effects which govern retention in ion exchange chromatography, one of the main factors affecting retention of carboxylic acids is the molecular adsorption of the acid on the anion exchange resin. The presence of

Figure 6 Analysis of human urine using ion exclusion chromatography. An Interaction ORH-801 column was used with a mobile phase comprising $10 \text{ mmol L}^{-1} \text{ H}_2\text{SO}_4$ containing 10% methanol. Detection was at 254 nm. Solute identities: 1, oxalic acid; 2, oxaloacetic acid; 3, α -ketoisovaleric acid; 4, ascorbic acid and α -keto- β -methyl-*n*-valeric acid; 5, β -phenylpyruvic acid; 6, uric acid; 7, α -ketobutyric acid; 8, homoprotocatechuic acid; 9, unknown; 10, unknown; 11, hydroxyphenylacetic acid; 12, *p*-hydroxyphenyllactic acid; 13, homovanillic acid. (Reprinted with permission from Woo DJ and Benson JR (1984) *American Clinical Products Review* Jan: 20.)

double bonds in carboxylic acids leads to higher retention factors, probably due to stronger hydrophobic interactions of the double bond with the polymeric matrix of the resin and also stronger electrostatic interactions between ionic groups. The presence of hydroxy groups in carboxylic acids increases the polarity of the acid and results in stronger interactions both with the aqueous mobile phase (leading to lower retention factors for the acids) and any alkanol substituent of the quaternary ammonium functional group of the anion exchange resin (leading to higher retention factors). Since the adsorption of carboxylic acids plays such an important role in the retention of these acids in ion exchange chromatography, the pK_a

values of the acids are also important, as are any parameters which influence the dissociation of the acid, such as the pH of the mobile phase and the concentration of any organic solvent. Additionally, the pH of the mobile phase may also affect its elution strength and hence affect retention as well.

Applications

Compared to other separation methods such as ion exclusion chromatography, anion exchange provides improved selectivity within the three groups of acids: mono-, di- and tricarboxylic acids. This is particularly true among the stronger acids such as most of

Figure 7 Example of a gradient separation of inorganic and organic acid anions by anion exchange chromatography. the di- and tricarboxylic acids. Of the di- and tricarboxylic acids which are in the Krebs cycle or are commonly found in foods, there are only two groups of co-eluting acids: malic and malonic, and isocitric and *cis*-aconitic. Another advantage of anion exchange separation is the possibility of simultaneous determination of some inorganic ions, such as fluoride, chloride, and sulfate, with the carboxylic acids.

Applications of anion exchange chromatography of carboxylic acids include the quantification of short chain organic acids and inorganic anions for the biotechnology, chemical or power industries, the separation of the Krebs cycle acids in foods and beverages, and also the separation of aromatic carboxylic acids in chemical process solutions and as impurities in precursors in the polymer industry.

Conclusion

Four modes of HPLC used in the separation of carboxylic acids have been discussed. Ion suppression chromatography, using a buffer to suppress the ionization of the acids, is the simplest separation system for carboxylic acids. Ion interaction chromatography offers the greatest variety of parameters to alter the selectivity of the separation system by changing the properties of the ion interaction reagent. Ion exclusion chromatography is the most commonly used method in the separation of carboxylic acids due to its compatibility with a wide range of sample matrices. Ion exchange chromatography provides improved

selectivity within groups of acids but the technique requires the use of gradient elution.

Introduction

The thin-layer chromatography (TLC) of aliphatic and aromatic acids having a wide range of structures has proved to be of great practical value in the chemistry and biochemistry of this large group of organic compounds. This review of the TLC properties of acids is firstly conveniently divided into a discussion of qualitative aspects of the relative hR_F values of various classes of aliphatic and aromatic carboxylic acids having a wide range of structures on different layers and in different solvent systems. Some mention is made of compounds with other acidic functions. Secondly, there is a selective account of applications on the quantitative determination of acids in typical current synthetic and some natural sources.

Acyclic and Cycloaliphatic Compounds

Alkanoic, Alkanedioic, Hydroxy, Keto, Unsaturated, Arylalkanoic Acids and Other Related Acids of Biological Significance

***n*-Alkanoic acid** The separation of these acids by the technique of TLC with respect to the lower homologous fatty acids has a historic precedent in that their separation in the vapour phase on a column coated with a stationary phase was the first published example of gas chromatography.

Although it might be generally considered that gas chromatography is more suitable than TLC for the

separation of alkanoic acids, Table 1 shows some simple conditions that have been used in this series typical of a partition separation. Many of the values quoted in the ensuing tables have been adapted from extensive published information by Hanai (see Further Reading). For comparison, the hR_F values of the dibasic acids malonic, succinic, glutaric and adipic in solvent a are 9, 14, 18 and 22 respectively, and that of glycolic acid, 38. The first four acids in the table have also been examined on crystalline cellulose impregnated with sodium bicarbonate in ethanol-water (100:20) and detection by dicyclohexyl carbodiimide to separate formic acid, acetic, propionic and butanoic acids having the hR_F values 31, 37, 45 and 52 respectively.

***n*-Alkanedioic acids** The saturated dibasic acids have been more widely studied on a variety of layers and solvents, as illustrated in Table 2 which again, as with the monobasic series, shows partition separations. In cases where a considerable number of solvents have been listed, the optimum conditions for the series of compounds have been given. For comparison, the hR_F value of glycolic acid under the conditions of g was 38. In another separation on silica gel (sil G25, Macherey Nagel) with the solvent *n*-pentyl formate-chloroform-formic acid (70:15:15) and detection by bromocresol green, nonlinearity was found in that malonic, succinic, glutaric and adipic acids had hR_F values of 40, 43, 54 and 48 respectively. Folic acid, which may be regarded as a 2-acylamino derivative of glutaric acid, had an hR_F value of 0 compared with 78 for nicotinic acid on silica gel G in water as developing solvent.

Hydroxy acids It is convenient to classify this group of saturated acids as monohydroxy, monohydroxy-

Table 1 hR_F values of homologous alkanoic acids on starch and on cellulose layers

Alkanoic acid	Conditions		Detection	
	a	b	a	b

Azelaic (C_9)					67		
Sebacic (C_{10})					72		
Undecyl (C_{11})					82		

a, Ethanol-concentrated ammonia-water (150:8:40), cellulose (Merck 5552); b, 2-ethyl-1-butanol-formic acid-water (40:12:48); c, diethyl ether-light petroleum- CCl_4 -water-formic acid (50:20:20:8:1); polyamide 6; d, ethanol-concentrated ammonia-water (100:16:12), cellulose MN300; e, di- n -butyl ether-formic acid-water (65:25:2.2), cellulose (Merck 5716); f, toluene-propionic acid-water (47:47:4.9), silica gel (Merck 5721); g, ethanol-concentrated ammonia-water (78:13:20), rice starch. (With acknowledgement to Hanai, 1982.) The use of formic acid diminishes streaking sometimes found in the TLC of acids in neutral solvents. It is thought that in acidic solvents the formation of a dimeric intermolecularly hydrogen-bonded species is then favoured in the equilibrium with the monomeric form, while in basic solvents the monomeric anion is largely present. Acidic adsorbents may likewise simulate acidic solvents.

(Modified with permission from Hanai, 1982.)

dibasic, monohydroxytribasic, dihydroxydibasic and polyhydroxy types. Table 3 lists the hR_F values of a number of acids with this functionality. For comparison, the hR_F value of malonic acid under condition f was 40 and in the aromatic series that of mandelic acid (α -hydroxyphenylacetic acid) was 57. In general, cellulose has been used as adsorbent in examples a to e and silica gel in f. In early work, silica gel G-kieselguhr (1:1), kieselguhr impregnated with polyethylene glycol and polyamide layers were also employed. It is possible that in acidic developing solvents certain of these acids are present as intramolecularly hydrogen-bonded structures and that five-membered are likely to be more stable than six-membered rings. Thus glycolic and lactic acids would be expected to have high hR_F values whereas acids having hydrogen-bonded rings and additional acidic groups would have lower values. Under basic conditions with ammonia the solutes are more polar

and the polarity of the developing solvent has to be increased by the use of ethanol. The meso and DL forms of tartaric acid show a small difference of hR_F which can be enhanced by the use of silica gel impregnated with boric acid. It is also possible to separate the enantiomers of racemic hydroxy acids by the incorporation of a chiral additive in the adsorbent layer. The role of impregnated layers has been reviewed by Hauck *et al.* (see Further Reading).

Keto acids The hR_F values of a number of mono keto derivatives of monobasic and dibasic acids are given in Table 4. The compounds shown from top to bottom in the table are glyoxylic, pyruvic, 2-oxobutanoic, 2-oxovaleric, 2-oxoisocaproic, oxaloacetic and 2-oxoglutaric acid. The need of formic acid in high concentration to effect a separation is illustrated in d compared with f. For comparison, the hR_F values under conditions d of citric and malic acids were 44 and 56 respectively. Intramolecular hydrogen bonding may account for the higher hR_F values of the monobasic compounds. The *cis* and *trans* 2,4-dinitrophenylhydrazones of a range of keto acids have been examined.

Unsaturated monobasic dibasic and polybasic acids

The unsaturated acids are a large group which have technical and medicinal uses. The majority are either di- or tribasic. Table 5 summarizes the hR_F values of a selection of compounds. Extensive details of separations have been described by Hanai and also in early work a limited range of monobasic keto-, hydroxy acids and of dibasic acids was studied. The separation of *cis* and *trans* isomers, for example maleic and fumaric acids, appears to be generally straightforward and free of the requirement for argentation TLC, as in the case of unsaturated fatty acids. The stereochemistry of the glutaconic acid described in Table 5 was not stated. The formulae of (1) *trans*-aconitic acid, (2) itaconic acid, (3) *trans*-glutaconic acid, (4) mesaconic acid (*trans*) and (5) citraconic acid (*cis*) are depicted.

Table 3 hR_F values of hydroxyacids on various layers

Acid	Conditions					
	a	b	c	d	e	f
Glycolic, HOCH ₂ CO ₂ H		67	46	50		31
Lactic, HOCH(CH ₃)CO ₂ H (DL)	76	72	73	89		36
Malic, HO ₂ CCH ₂ CH(OH)CO ₂ H (DL)	29	30	32	35	50	26
Citramalic, HO ₂ CCH ₂ C(Me)(OH)CO ₂ H						65

Ascorbic						15

a, Diisopropyl ether–formic acid, (3:1), cellulose MN 300HR, detection by UV; b, ethanol–concentrated ammonia–water, (150:8:40), cellulose, (Merck 5552), detection by bromocresol green or starch–iodine reagent; c, 2-ethyl-1-butanol–formic acid–water, (40:12:48), cellulose, (Merck 5552), detection as in b; d, diisopropyl ether–formic acid–water, (65:25:10), cellulose (Merck 5716), detection by aniline–xylose, furfural; e, propanol–methyl benzoate–90% formic acid–water, (7:3:2:1), cellulose, detection by Pásková and Munk reagent; f, *n*-pentyl formate–chloroform–formic acid, (70:15:15), silG25, detection by bromocresol green. (With acknowledgement to Hanai, 1982.)

Arylalkanoic acids Prior to an account of the TLC properties of aromatic acids it is of interest to note those of the semi-aromatic group typified by phenylacetic acid and its homologues and analogues. The hR_F values of a range of these compounds are shown in Table 6. The need to use the least polar combination of solvents is illustrated by the conditions with c and d where the latter is ineffective while the former affords a separation of homologous compounds. In the case of the unsaturated compound, the separation in conditions d would almost certainly be improved with argentated silica gel.

Acidic Compounds of Biosynthetic and Biological Importance

A number of polyfunctional cyclohexanyl derivatives classifiable in several of the above groups are (6) shikimic acid, (7) mevalonic acid and (8) abscisic acid, all of which have biological significance. Their TLC properties in a number of solvents have been described.

Table 4 hR_F values of keto acids on various layers

Keto acid	Conditions				
	a	b	c	d	e
OHCCO ₂ H	50		37	55	43

<i>cis</i> -Aconitic	1					4	65		
<i>trans</i> -Aconitic	9	35	9	78			57		

a, Toulene-propionic acid–water, (47:47:4.9), cellulose (Merk 5716), detection by aniline-xylose, furfural; b, diisopropyl ether–formic acid (3:1), cellulose MN300HR, detection by di-chlorofluorescein; c, diethyl ether–formic acid–water, (10:2:1), cellulose (DC Fertigplatten) detection by fluorescence; d, 95% ethanol–25% ammonia–water (8:2:1), same layer and detection as c; e, diisopropyl ether–light petroleum–carbon tetrachloride–water–formic acid (50:20:20:8:1), polyamide 6, detection by K ferricyanide, ferric ammonium sulfate; f, *n*-pentyl formate–chloroform–formic acid (20:70:10), sil G25, detection by bromocresol green; g, propanol–methyl benzoate–90% formic acid–water (7:3:2:1), layer not stated but probably cellulose, detection by Pásková and Munk reagent; h, butyl formate–ethyl acetate–formic acid (82:9:9), polyamide, bromocresol green; i, diisopropyl ether–formic acid–water, (90:7:3) silica gel, bromocresol green. (With acknowledgement to Hanai, 1982 and to Copius-Peereboom, 1969.)

Shikimic acid (6), a hydroxy unsaturated cyclic compound, in the solvent g (Table 5) had an hR_F of

Table 6 hR_F values of derivatives and homologues of phenylacetic acid

Acid	Conditions			
	a	b	c	d
Phenylacetic	68	74	54	95
4-Phenylbutanoic			75	95
4-Phenylbut-3-enoic			71	95
Phenoxyacetic	64	63		
<i>trans</i> -Cinnamic			67	95

a, *n*-pentyl formate–chloroform–formic acid, (70:15:15), sil G25, bromocresol green; b, *n*-pentyl formate–chloroform–formic acid (20:70:10), sil G25; c, light petroleum–acetic acid, (49:1), silica (Eastman), bromocresol green; d, light petroleum–diethyl ether–formic acid, (45:5:1), silica (Eastman). (With acknowledgement to Hanai, 1982.)

Table 7 The hR_F values of cyclohexane- and dienecarboxylic acids (dihydro- and tetrahydro-derivatives of benzoic acid)

Compound	Conditions	
	a	b
Cyclohexanecarboxylic acid	83	92
Cyclohexa-1-enecarboxylic acid	91	95
Cyclohexa-3-enecarboxylic acid	91	95
Cyclohexa-1,4-dienecarboxylic acid	77	83
Cyclohexa-2,5-dienecarboxylic acid	77	82
Benzoic acid (cyclohexa-1,3,5-trienecarboxylic)	77	88
2-Hydroxycyclohexanecarboxylic acid	54	21

a, Benzene–dioxane–acetic acid (90:25:4), kieselgel G, detection by autoradiography; b, light petroleum–diethyl ether–acetic acid (50:50:1), as before in a. (With acknowledgement to Hanai, 1982.)

32. The hR_F value of the keto hydroxyacid, mevalonic acid, in diethyl ether–formic acid (7:1) on silica gel (Eastman) was 29 and that of abscisic acid in *n*-propanol–25% ammonia–water (80:10:10) on kieselgel (HF254) was 57. The rooting hormone, indole-3-acetic acid, under the same conditions was 45.

The hR_F values of other cyclic compounds which are metabolites of benzoic acid and also structurally related to shikimic acid are given in Table 7 alongside the reference compound benzoic acid. Isomeric compounds were not separable, although by the use of argentation TLC this may be possible.

Aromatic Acidic Compounds

Substituted Benzoic Acids

In this category the compounds under consideration are those in which the carboxyl group is directly attached to the aryl ring.

The isomeric hydroxybenzoic acids have been listed in the section on phenols. In Table 8 the TLC properties of the aminobenzoic acids are given alongside the reference compounds benzoic acid, 2-hydroxybenzoic acid, 2,4-dihydroxybenzoic acid, 3,4,5-trihydroxybenzoic acid (gallic acid) and phthalic acid.

The hR_F values of a wide range of other phenolic acids have been recorded, as have those of more complex compounds, the polycyclic series of lichen acids. In the case of *cis* and *trans* isomers of aromatic acids having an unsaturated side chain, separations do not seem to be difficult. Thus, on silica gel 60 (F₂₅₄) with diethyl ether–hexane–chloroform–acetic acid (12:38:50:0.5) the hR_F values of *cis*- and *trans*-3,4-dihydroxycinnamic acid were 18 and 27 and of the corresponding isomers of

Table 8 hR_F values of aminobenzoic acids and some hydroxybenzoic acids

Acidic compound	Conditions					
	a	b	c	d	e	f
Benzoic	53	15	72	69	79	
2-Aminobenzoic	38					
3-Aminobenzoic	28					
4-Aminobenzoic	24					
2-Hydroxybenzoic	55			72	78	54
2,4-Dihydroxybenzoic	19					30
3,4,5-Trihydroxybenzoic	4					11
Phthalic	17			55	41	

a, Ethanol–butanol–water–concentrated ammonia (40:30:15:15), rice starch, detection by UV; b, *n*-hexane–acetic acid (96:4), SIF silica gel sheet, UV; c, same as b, cellulose-TLC alumina, UV; d, *n*-pentyl formate–chloroform–formic acid (70:15:15), sil G25, detection by bromocresol green; e, *n*-pentyl formate–chloroform–formic acid (20:70:10), same as d, UV; f, 2-butanone–methyl phenyl ketone–50% acetic acid (5:5:4), poly-*N*-vinylpyrrolidone–gypsum, detection by molybdate, diazotized sulfanilic acid, phloroglucinol. (With acknowledgement to Hanai, 1982.)

4-hydroxy-3,5-dimethoxycinnamic acid, 43 and 55 respectively.

The effect of the aryl nucleus, Ar, on the hR_F value of the acid ArCO_2H is seen with benzoic, naphthalene-2-carboxylic and diphenyl-2-carboxylic acids, which are 53, 70 and 75 respectively with the solvent ethanol–butanol–water–conc ammonia (40:30:15:15) and the adsorbent, rice starch. The water-soluble vitamin, nicotinic acid (pyridine-3-carboxylic acid) on sil G25 had an hR_F value of 5 in *n*-pentyl formate–chloroform–formic acid (70:15:15), while that of benzoic acid was 69.

The hR_F values of the isometric benzenedicarboxylic and certain polybasic reference acids were the subject of early studies under a variety of conditions and are shown in Table 9.

More recent experiments on the separation of the dicarboxylic acids have been carried out with chloroform–tetrahydrofuran (2:1) on silufol in the presence of an ion pair reagent but the separations described earlier were just as effective.

The influence of the substituent position on the hR_F values of substituted benzoic acids has been studied with reference to amino, nitro, chloro, hydroxy and carboxy compounds, although nothing appears to have been described on the separation of the isomeric toluic acids. However, there has been extensive work by Guinchard *et al.* (see Further Reading) on (1) benzoic acid compared with (2) 2-chloro, (3) 3-chloro, (4) 4-chloro, (5) 2-hydroxy, (6) 3-hydroxy, (7) 4-hydroxy, (8) 2-nitro, (9) 3-nitro, (10) 4-nitro, (11) 2-amino and (12) 4-aminobenzoic acid. Figure 1

depicts the effect on the R_F of small changes in the aqueous formic acid concentration in benzene when this range of acids was chromatographed on silica gel G.

Figure 2 depicts the effect on the R_F value of the same series when run in benzene containing diethyleneglycol monoethyl ether with various concentrations of formic acid. Separation of all 12 acids can be achieved in either system with the appropriate formic acid concentration. The more polar compounds have lower R_F values than the less polar ones.

By contrast, under reversed-phase conditions with benzene as the developing solvent, Figure 3 shows the separations of a number of 2-substituted benzoic acids on silanized silica gel (RP-8) with various aqueous organic solvents (organic solvent–water, 40:60, v/v) containing 0.1 mol L^{-1} tetramethylammonium bromide. With this system the more polar solutes have higher R_F values.

An extensive range of adsorbents and solvents for a variety of aromatic carboxylic acids have been summarized by Tyman (see Further Reading).

While carboxylic acids have been the main group of acidic compounds studied, by contrast sulfonic acids RSO_3H , of both aliphatic and aromatic origin, have received little attention. 1-*N*-Acylamino-8-hydroxynaphthalene-3,6-disulfonic acid derivatives of interest for anti-human immunodeficiency virus activity have been studied on S III Chromarods with methanol or methanol–chloroform–ammonia (35:55:10) as solvents.

Sulfuric esters, ROSO_3H of substituted phenols, have been examined on silica gel G with benzene–butanone–ethanol–water (30:30:30:10). The less acidic group, for example the sulfonamides, $\text{NH}_2\text{C}_6\text{H}_4\text{SO}_2\text{NHR}$ (where R comprises a wide variety of

Table 9 The hR_F values of carboxy derivatives of benzoic acid

Acid	Conditions			
	a	b	c	d
Phthalic (1,2)	51	30	39	36

Hexahydrophthalic	60	65	79	66

a, Diisopropyl ether–formic acid–water (90:7:3), silica gel; b, same as b but saturated with polyethylene glycol M 1000 kieselguhr impregnated with polyethylene glycol; c, diisopropyl ether–light petroleum–carbon tetrachloride–formic acid–water (50:20:20:8:1), polyamide; d, butyl formate–ethyl acetate–formic acid (82:9:9), same polyamide as c. (With acknowledgement to Copius-Peereboom, 1969.)

Figure 1 R_F values of aromatic carboxylic acids in benzene containing formic acid. 1, Benzoic; 2, 2-chloro; 3, 3-chloro; 4, 4-chloro; 5, 2-hydroxy; 6, 3-hydroxy; 7, 4-hydroxy; 8, 2-nitro; 9, 3-nitro; 10, 4-nitro; 11, 2-amino; 12, 4-aminobenzoic acids. (Reproduced with permission from Guinchard *et al.*, 1976.)

groups), has been examined in detail. Monoalkyl phosphate esters, ROP(O)(OH)_2 , dialkyl esters, $(\text{RO})_2\text{P(O)OH}$ and monoalkylphosphonic acids RP(O)(OH)_2 do not seem to have been examined by TLC.

Visualizing Agents for Aromatic Carboxylic Acids

In this article, reference has frequently been made to the detection of acids with bromocresol green and other systems. Some other reagents for aromatic carboxylic acids are hydrogen peroxide or alkaline potassium permanganate. Several new visualizing agents and sodium hydroxide (10% aqueous solution) were compared with respect to the minimum quantity of acid detectable (μg per spot) and the type of layer. Generally, of the three layers, silica gel 60 GF_{254} , silica gel-kieselguhr mixtures and polyamide, the first was preferred. Although the minimum detectable amount of solute varied with the 13 different solutes and the 12 different visualizing agents examined, thymol blue detected all the solutes while bromothymol blue and bromocresol green detected all but 4-hydroxybenzoic acid and 3-hydroxycinnamic acid respectively with silica gel as adsorbent.

Quantitative TLC Determination of Organic Acids in Synthetic and Natural Mixtures

Examples of the application of TLC for the quantitative determination of a variety of acids in edible, potable and polymeric products are discussed in this section. Many simple aliphatic acid aromatic acids, notably benzoic acid, citric and sorbic acids, are employed in edible materials such as preservatives while salicylic acid and its acetyl derivative appear in numerous pharmaceutical preparations. Accordingly, their quantitative determination is important and for such analyses planar methods have been widely used. Some typical quantitative applications are described in detail.

HPTLC Determination of Organic Acid Preservatives in Beverages

In a high performance TLC (HPTLC) method sorbic acid (2,4-hexadienoic acid) and benzoic acid were determined without preliminary extraction or clean-up by the chromatography of aliquots of samples and of standards on preadsorbent silica gel or C_{18} -bonded silica gel plates containing fluorescent indicator.

Figure 2 R_F values of aromatic carboxylic acids. 1, Benzoic; 2, 2-chloro; 3, 3-chloro; 4, 4-chloro; 5, 2-hydroxy; 6, 3-hydroxy; 7, 4-hydroxy; 8, 2-nitro; 9, 3-nitro; 10, 4-nitro; 11, 2-amino; 12, 4-aminobenzoic acid in benzene containing formic acid and diethylene glycol monoethyl ether. (Reproduced with premission from Guinchard *et al.*, 1976.)

The zones which quenched fluorescence upon UV irradiation at 254 nm were compared by scanning densitometry. This procedure was preferred to measurement of densitometry based on UV absorption.

Preadsorbent high-performance LHPKDF silica gel (Whatman) plates (20 × 10 mm) with 19 lanes were used for normal-phase experiments with the solvent *n*-pentyl formate–chloroform–formic acid (2 : 7 : 1) in which the R_F values for sorbic acid and benzoic acid were 61 and 58. For reversed-phase TLC on (Whatman) C_{18} LKC₁₈F plates (20 × 20 mm) with methanol–0.5 mol L⁻¹ sodium chloride (1 : 1), the respective R_F values for these two acids were 44 and 59. It was found necessary to apply a stream of warm air during spotting of samples with a 10 μ L Drummond digital microdispenser and, after this stage, to dry the plates. Development was then effected in a Camag twin-trough chamber to 7 cm beyond the sorbent–preadsorbent interface with normal-phase plates and to 10 cm for C_{18} plates. The plates were then dried and the areas of the dark quenched zones against a fluorescent background were scanned at the

predetermined maximum absorption (between 200 and 370 nm) with a Shimadzu Model 930 densitometer operated in the reflectance mode. From the chromatography of 0.50, 1.00, 2.00, 4.00, 6.00 and 8.00 μ L of standards for sorbic and benzoic acids containing 125–2000 ng and 1.00–16.0 μ g respectively, linear calibration plots of scan area/weight were obtained. For quantification, the sample scan area was compared with that of a closely matching standard within the linear calibration range and the corresponding weight found. Recovery analyses were carried out with beverage samples spiked with sorbic and benzoic acids, which were compared with the corresponding unfortified samples. They averaged at 98.0% for all analyses.

By the HPTLC method, sorbic and benzoic acids present separately in a variety of beverages have been directly quantified. The analysis of standards on the same TLC plate eliminates the requirement for an internal standard, as in high performance liquid chromatography (HPLC). By contrast with the HPTLC and HPLC methods, spectrophotometric

Figure 3 R_F values of 2-substituted benzoic acids in different solvents. (Reproduced with permission from Jost *et al.*, 1984.)

analysis requires a preliminary sample preparation by steam distillation. However, very low concentrations of benzoic acid are more amenable to HPLC analysis and when sorbic and benzoic acids are present together the method is less satisfactory due to sample streaking, even on a C_{18} -bonded silica gel layer (particularly at higher loads).

In view of these limitations, a modified method was adopted, involving solid-phase extraction (SPE) on a C_{18} cartridge followed by the preceding quantification method established on preadsorbent C_{18} plates.

The extraction procedure was validated by spiking commercial samples with known amounts of the acids in turn and demonstrating the satisfactory recovery of each. With this total method, sample interferences were eliminated and samples too low for analysis by direct spotting could be analysed. The whole TLC methodology is considered to be applicable to a wide range of solid and syrupy-type samples containing either or both of the two preservatives at concentrations as low as those measurable by HPLC.

Quantitative Fluorescence Densitometry for the Analysis of Rosmarinic Acid

Rosmarinic acid (9), a useful natural antimicrobial compound of potential interest to the food industry, occurs in eel grass (*Zostera marina*) from which it is extractable together with a number of other phenolic acids. It has been directly quantitatively and rapidly analysed by an HPTLC densitometric method which utilized the fluorescence of the material upon excitation at 366 nm.

Crushed leaves (200 mg) of the natural product were extracted with 5% acetic acid-methanol (1:2) accompanied by ultrasonication during 30 min. The extract was filtered and then employed for direct HPTLC on plates (10 × 20 cm) pre-coated with cellulose without fluorescent indicator. Samples and standard solutions (2 µL) were applied to plates as 7 mm wide bands with a Linomat IV applicator under a pressure of 2.5 bar; this was developed in a twin-trough chamber with 3% sodium chloride in 0.5% acetic acid-acetonitrile-tetrahydrofuran (100:24:1) until the solvent had migrated 4.5 cm. The dried plate was irradiated with a mercury vapour lamp and the resultant fluorescence emission measured through a cut-off filter (400 nm) by scanning with a TLC scanner II (Camag) equipped with CATS software (version 3.14).

Plots of either peak area or height/concentration were linear over concentration range 0.1–0.6 mg mL⁻¹ (i.e. 0.2–1.2 µg) and the weight of rosmarinic acid in unknown samples was readily found.

Densitometric Analysis of Gallic Acid in Fermentation Liquors

One of the ways used for obtaining gallic acid (3,4,5-trihydroxybenzoic acid), an important intermediate in synthesis for the pharmaceutical and food industries, is by the acid hydrolysis of natural gallotannins, for example from gall nuts, tara pods or sumac leaves. In an enzymatic procedure hydrolysis of these types of raw material with a fungal tannin acylhydrolase which cleaves depside bonds, the monitoring of a large number of samples by a simple and rapid TLC method was investigated as a potential alternative to HPLC analysis.

Crude samples from enzymatic solutions were diluted between one- and 100-fold with methanol and

filtered through a Minisart NML 0.45 µm filter and gallic acid used at known concentrations as an internal standard. TLC analysis was performed on glass plates (5 × 20 cm), coated with a 0.25 mm layer of RP-18 F₂₅₄ (Merck 15683); the glass plates were pre-cleaned with a single development in methanol. Samples (6 µL) were applied with a Linomat IV spotter and then developed to a distance of 12 cm, with M aqueous acetic acid-methanol (1:1) for 2 h. Densitometry was effected by spectrophotometry and a mercury light source (254 nm) in the absorbance mode, to determine extinction of fluorescence, as an area measurement, with a TLC scanner II (Camag) controlled by CATS software. Calibration plots were found to be near to linearity with between 10 and 75 µg gallic acid on the plate when the ratios of the peak area of the acid to the internal standard were between 0.3 and 1.5, although in practice ratios of areas between 0.5 and 1.25 (corresponding to gallic acid between 25 and 62.5 µg) were adopted in the analytical method. An inherent difficulty was found to be slight inhomogeneity in the coating of the fluorescent indicator: to improve on this, the plate was scanned before an assay to determine any background fluorescence, which was then subtracted to 'zero' the plate. With this proviso and by the use of the strict linearity range, the values obtained for gallic acid were 98 ± 2.1% of those found by HPLC.

Determination of Diacetonegulonic acid (DAG) in Water Samples

DAG (10) is the penultimate intermediate in the synthesis of ascorbic acid (vitamin C) and for many years was discharged in waste surface waters. This led to contamination of groundwaters and, although it is not toxic to humans, it has an inhibitory effect on the growth of grasses. Current European drinking water regulations restrict its concentration to 0.1 µg L⁻¹. A fast and efficient HPTLC method has been described.

Due to the low concentration of DAG, SPE is used for sample preparation. Because of the sensitivity of DAG to silica gel and, more particularly to acidic solutions, it was found necessary to adjust the water sample for analysis to no less than pH 4 and to effect SPE with Polyspher RP-18 (a 35 μm polystyrene-divinylbenzene polymer with C_{18} side chains) which gave a 100% recovery. For the extraction a cartridge (0.2 g) was first conditioned successively with ethyl acetate, methanol and water at pH 4 (1 cm^3 of each), after which the water sample for analysis adjusted to pH 4 (20 cm^3) was aspirated through the cartridge. The cartridge was dried in a stream of nitrogen and then eluted with ethyl acetate (2 \times 1 cm^3) and the eluate after treatment with one drop of ammonia evaporated at less than 40°C to leave 0.5 cm^3 , an aliquot of which was applied to an PTLC silica gel 60 F₂₅₄ pre-coated plate (10 \times 20 cm). In the case of original concentrations of less than 5 $\mu\text{g L}^{-1}$, the total eluate was used for TLC.

For analysis of sample volumes up to 20 μL , multiple development one-dimensionally with solvent A, chloroform-methanol (80:20) to 8 cm and then after drying, solvent B (chloroform-methanol-glacial acetic acid, 80:20:2) for 6.5 cm was carried out. Alternatively, two-dimensional development was carried out with the same two solvents, distances and drying. Spots or streaks were detected by immersion of the plate in an ethanolic solution of 4-methoxybenzaldehyde containing sulfuric acid, followed by drying and heating at 130°C for 2–3 min to form red fluor-

escent areas which were visible under UV light (366 nm) and quantified with a TLC scanner. Two-dimensional development was advocated for samples with less than 5 $\mu\text{g L}^{-1}$ DAG, while for higher concentrations, one-dimensional development was adequate. The calibration of peak area/weight DAG was linear within the range 0.125–1.5 μg . It was found that for the determination of higher concentrations it was essential to apply DAG as streaks to preserve linearity over the range of concentrations and it was then established that from 0.25 to 250 μg could be analysed with consistent accuracy.

The SPE procedure followed by TLC appears to be superior to derivatization followed by GC-MS and it was considered that very small concentrations of DAG could even be estimated visually without any instrumentation, thus generally giving an inexpensive procedure. Other application of quantitative TLC to the analysis of humic acids in natural waters, 6-aminocaproic acid (12), ϵ -caprolactam in polyamide-6 (11) and to uric acid (13), creatine (14) and creatinine (15) mixtures in biological materials have been described.

Conclusions

Acids of simple and more complex structures are components of many edible, technical and medicinal products and TLC affords an ideal approach for their analysis because no derivatization is required and a wide variety of detection methods is applicable for their qualitative and quantitative determination. It can be envisaged that the use of HPTLC, of special layers and the employment of combined techniques will continue to extend and expand the planar approach to the analysis of acidic compounds.

AFLATOXINS AND MYCOTOXINS

Chromatography

Introduction

Mycotoxins have been defined as 'fungal metabolites which, when ingested, inhaled or absorbed through the skin, cause lowered performance, sickness or death in man or animals, including birds'.

Exposure to mycotoxins can produce both acute and chronic toxic effects ranging from death to deleterious effects on the central nervous, cardiovascular and pulmonary systems, and on the alimentary tract. Mycotoxins may be carcinogenic, mutagenic, teratogenic and immunosuppressive. The ability of some mycotoxins to compromise the im-

mune system and, consequently, to reduce resistance to infectious disease, is now widely considered to be their most important effect.

The mycotoxins attract worldwide attention because of the significant economic losses associated with their impact on human health, animal productivity and both domestic and international trade. It has been estimated, for example, that annual losses in the USA and Canada arising from the impact of mycotoxins on the feed and livestock industries are in the order of US\$5 billion. In developing countries where the food staples (e.g. maize and groundnuts) are susceptible to contamination, significant additional losses amongst the human population are likely, because of morbidity and premature death associated with the consumption of mycotoxins.

It is likely that mycotoxins have plagued mankind since the beginning of organized crop production. Ergotism (St Anthony's Fire), for example, which is caused by the consumption of rye contaminated with the 'ergot alkaloids', is discussed in the Old

Testament, and reached epidemic proportions in many parts of Europe in the tenth century.

Mycotoxins of Worldwide Importance

An 'important' mycotoxin will have demonstrated its capacity to have a significant economic impact on the exposed human and/or animal population. Those moulds and mycotoxins that are currently considered to be of worldwide importance are shown in **Table 1**, and the chemical structures of the mycotoxins in **Figure 1**.

Aflatoxins

The term 'aflatoxins' was coined in the early 1960s when the deaths of thousands of turkeys ('Turkey X' disease), ducklings and other domestic animals were attributed to the presence of *Aspergillus flavus* toxins in groundnut meal imported from South America. The acute and chronic effects of the aflatoxins on a wide variety of livestock are now well documented, and include death, decreased productivity, and increased susceptibility to disease. Aflatoxin B₁ is a human carcinogen and one of the most potent hepatocarcinogens known. Human fatalities have resulted from the consumption of heavily aflatoxin-contaminated foods, frequently when wholesome food is in short supply. Aflatoxin M₁ occurs in milk, and is produced by the bovine metabolism of aflatoxin B₁ when contaminated feed is ingested by dairy cows.

Trichothecenes

T-2 toxin, deoxynivalenol (and nivalenol) belong to a large group of structurally related sesquiterpenes known as the 'trichothecenes', which occur primarily in cereals. T-2 toxin is the probable cause of 'alimentary toxic aleukia' (ATA), a disease that affected thousands of people in Siberia during the Second World War, and led to the elimination of entire villages. The symptoms of ATA include fever, vomiting, acute inflammation of the alimentary tract and a variety of blood abnormalities. The same toxin is also

associated with outbreaks of haemorrhagic disease in animals and with neurotoxic effects in poultry. An important effect of T-2 toxin (and other trichothecenes) is the immunosuppressive activity which has been clearly demonstrated in experimental animals.

Deoxynivalenol (DON) is probably the most widely occurring *Fusarium* mycotoxin. (The trivial name of 'vomitin' has also been accorded to DON because of outbreaks of emetic (and feed refusal) syndromes, amongst livestock, caused by this toxin.) The ingestion of DON has caused acute human mycotoxicoses in India, China and rural Japan. The Chinese outbreak, in 1984–85, was caused by mouldy maize and wheat. Symptoms occurred within 5 to 30 min and included nausea, vomiting, abdominal pain, diarrhoea, dizziness and headache.

Zearalenone

Zearalenone is an oestrogenic mycotoxin that is co-produced with DON, and which has been implicated, with DON, in outbreaks of acute human mycotoxicoses. In livestock, exposure to zearalenone-contaminated maize has caused hyperoestrogenism, especially in pigs, characterized by vulvar and mammary swelling and infertility.

Fumonisin

Fumonisin B₁ (FB₁) occurs in maize produced in a variety of agroclimatic zones. Two animal species, horses and pigs, are particularly targeted by FB₁. Exposure to FB₁ causes leukoencephalomalacia (LEM) in horses and pulmonary oedema in pigs. The presence of fumonisins in maize has been linked with human oesophageal cancer in the Transkei (South Africa) and China.

Ochratoxin A

Ochratoxin A (OA) causes nephropathy and immunosuppression in several animal species, and is carcinogenic in experimental animals. OA has been linked to the human disease Balkan endemic

Table 1 Moulds and mycotoxins of worldwide importance

Mould species	Mycotoxins produced	Main sources
<i>Aspergillus parasiticus</i> <i>A. flavus</i>	Aflatoxins B ₁ , B ₂ , G ₁ , G ₂ Aflatoxins B ₁ , B ₂	Edible nuts, oilseeds and cereals
<i>Fusarium sporotrichioides</i> <i>F. graminearum</i>	T-2 toxin Deoxynivalenol (or nivalenol in some areas) zearalenone	Wheat and Maize Wheat and Maize
<i>F. moniliforme</i> <i>Penicillium verrucosum</i> and <i>A. ochraceus</i>	Fumonisin B ₁ Ochratoxin A	Maize Wheat, barley, coffee beans, vine fruits

Figure 1 Mycotoxins of worldwide importance.

nephropathy, a fatal, chronic renal disease occurring in limited areas of Bulgaria, the former Yugoslavia and Romania. It has been suggested that pork products are significant human dietary sources of OA.

Control of Mycotoxins

The control of mycotoxins is summarized in Figure 2. The interventions that may be employed for the con-

trol of mycotoxins are prevention of contamination, identification and segregation of contaminated material (quality control, monitoring and legislation), and detoxification.

Preventative measures that militate against the onset of biodeterioration and, subsequently, the production of moulds and mycotoxins, may be introduced throughout the commodity system. However, the preharvest control of biodeterioration is somewhat

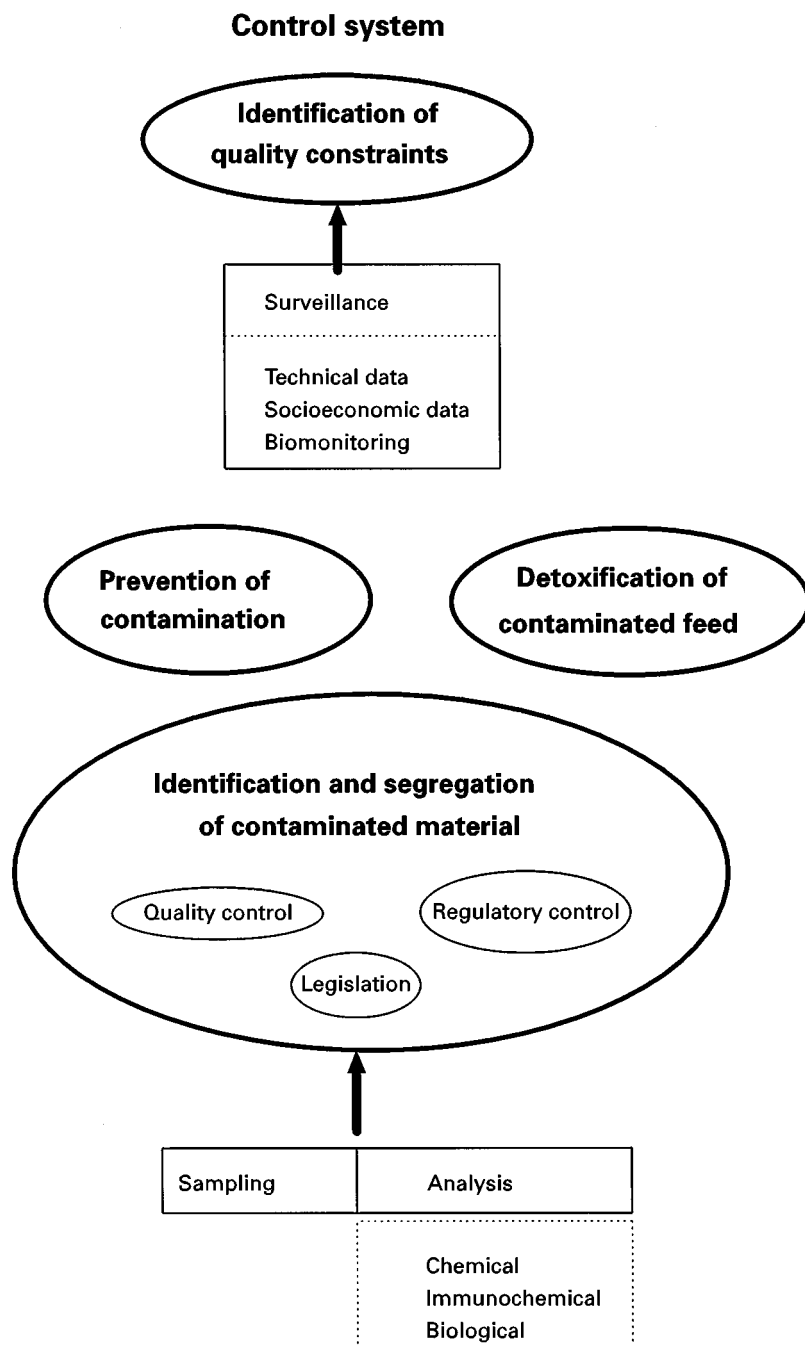

Figure 2 The mycotoxin control system.

compromised by our inability to control the climate! Attempts have been made to prevent preharvest contamination by breeding for resistance to moulds and by 'biocontrol' methods, involving the introduction, to the field, of atoxigenic strains of competing fungi. After harvest, it is important that the crop is dried to a 'safe' moisture level (which will not support the growth of moulds and mycotoxins) as quickly as possible.

The identification and segregation of mycotoxin-contaminated material may be pursued through quality control and regulatory procedures. More than 50 countries currently impose legal limits on the occurrence of mycotoxins (especially the aflatoxins) in foods and feeds.

Commercial detoxification plants, for the treatment of aflatoxin-contaminated groundnut meal, are currently operating in Senegal, France and the UK. The chemical detoxification reagent that is most widely used is ammonia, both as an anhydrous vapour and an aqueous solution.

If the package of control procedures described above is to be successfully implemented, it is essential that it is underpinned by an integrated package of sampling, sample preparation and analytical procedures.

Analysis of Mycotoxins

Worldwide, 5 parts per billion ($\mu\text{g kg}^{-1}$) is the most common maximum level of total aflatoxins permitted in foods. Similarly, aflatoxin M₁ is regulated in at least 14 countries, the permitted levels typically falling within the range 0.05 to 0.5 parts per billion. Consequently, it is essential that the analytical methods used for quality control and monitoring

(regulatory control) purposes are accurate and precise at these extremely low concentrations.

Analytical Sequence

The analysis of mycotoxins may be considered in terms of a sequence of four operations: extraction, clean-up, quantification and confirmation. Some of the more commonly used procedures associated with these operations are illustrated in Table 2.

The mycotoxin(s) under investigation must first be extracted from the complex and variable chemical milieu of the food or feed under investigation, using an appropriate extraction solvent. Commonly used solvent systems include acetone, acetonitrile, methanol, ethyl acetate, chloroform and water, either singly or as mixtures of two or more solvents. The extraction is performed either by shaking the mixture of sample and solvent for 30–45 min or by blending at high speed for approximately 3 min. The choice of solvent can significantly affect the extractability of the mycotoxin. The extraction of the aflatoxins from corn, for example, is significantly enhanced if the aqueous extraction solvent contains acetone as opposed to methanol. Supercritical fluid extraction is an emerging alternative to liquid extraction, and has been successfully applied to the extraction of aflatoxin B₁ from corn.

The crude extract, obtained after filtration of the shaken or blended mixture, is cleaned-up in order to remove as much non-mycotoxin material as possible, since the presence of extraneous compounds can seriously diminish the efficiency of the analysis. Clean-up procedures include liquid–solid extraction (defatting), liquid–liquid partitioning, chemical adsorption and chromatographic methods.

Table 2 The analysis of mycotoxins

<i>Operation</i>	<i>Commonly used procedure</i>
Extraction	Sample extracted by shaking or blending with chloroform, or mixtures of water/methanol, water/acetonitrile or water/acetone
Clean-up	Liquid–liquid partitioning or liquid–solid extraction Chemical adsorption Solid-phase extraction (SPE) Multifunctional clean-up column Chromatography Immunosorbent columns
Quantification	Thin layer chromatography (TLC) High performance thin layer chromatography (HPTLC) High performance liquid chromatography (HPLC) Gas chromatography (GC) Fluorimetry
Confirmation	Cochromatography Visual observation of colour change after derivatization Spectroscopy (with or without derivatization) Mass spectrometry

Solid-phase extraction (SPE) and immunosorbent columns are examples of recently introduced clean-up procedures that are now frequently used. SPE cartridges are available with a wide variety of polar, nonpolar and ion exchange bonded phases.

A 'multifunctional clean-up column' (MFC), composed of lipophilic, dipolar and anion exchange sites, reportedly affords the efficient clean-up of acetonitrile/water extracts within 10 s. MFC high performance liquid chromatography (HPLC) analysis methods have been applied to at least 10 mycotoxins.

The chromatographic quantification techniques used for the determination of mycotoxins in cleaned-up extracts include thin-layer chromatography (TLC), high performance TLC (HPTLC), high performance liquid chromatography (HPLC), and gas chromatography (GC). Worldwide, TLC is the most common method employed for the estimation of mycotoxins.

No assay can be considered as complete until the presence of the presumptive mycotoxin has been confirmed. This is especially important when an unusual commodity is under investigation. The ultimate confirmation involves the comparison of the physico-chemical characteristics of the presumptive mycotoxin with those of a standard compound. Such a course of action is not normally utilized as a routine procedure. Confirmatory techniques used in conjunction with HPLC include mass spectrometry and ultraviolet spectroscopy. When TLC or HPTLC are used for quantification, the formation of derivatives with characteristic chromatographic and fluorescence properties is commonly employed to confirm the presence of the presumptive mycotoxin(s).

Analytical Accuracy

The overall accuracy of the determination of mycotoxins will be governed by the combined effects of the sampling, sample preparation and analytical components of the analytical process. Undoubtedly, the sampling component is currently the greatest source of analytical error. Until effective sampling (and sample preparation) procedures have been developed for a variety of mycotoxin/commodity combinations, the accuracy and precision of methods for the determination of mycotoxins will be severely compromised.

The reliability of an analytical procedure may be expressed in terms of the accuracy, precision and limit of detection of the method. Interlaboratory precision is determined by the implementation of check-sample and collaborative studies. The level of interlaboratory precision for the determination of mycotoxins is still disappointing. A review of the reliability of mycotoxin assays, conducted in 1993,

indicated that little or no improvement in interlaboratory precision had occurred over the previous 20 years. The precision of TLC and HPLC methods were reportedly similar, whereas the precision of enzyme-linked immunosorbent assay (ELISA) methods was somewhat poorer. A series of proficiency testing exercises were carried out during 1993 and 1994 involving those European laboratories who contribute analytical data on food contamination to the World Health Organization (WHO) Global Environmental Monitoring Scheme (GEMS). The tests were performed according to the International Organization for Standardization/International Union of Pure and Applied Chemistry/Association of Official Analytical Chemists (ISO/IUPAC/AOAC) International Harmonized Protocol, and laboratories were awarded 'z scores' that signified their analytical capability. Eighty eight per cent of the laboratories obtained results of acceptable accuracy for the determination of the aflatoxins, whereas only 53% of the laboratories demonstrated acceptable accuracy for patulin (a mycotoxin produced by *Penicillium expansum* and other moulds.)

Simple Methods

Methods of quantification employing HPTLC, HPLC and GC require expensive equipment and skilled personnel. However, such procedures are not normally available in the basic analytical laboratories that exist in, for example, exporting developing countries and in some food and feed manufacturing plants.

Basic laboratory environments require simple, robust, low-cost methods that can afford reliable results in the hands of semiskilled operators. Methods that have been developed with such an application in mind include minicolumn and immunodiagnostic procedures. The minicolumn approach utilizes small glass columns packed either with selected chromatographic adsorbents or with other inorganic adsorbing materials. Minicolumns are used either to clean up the crude extract before quantification; or the mycotoxin under test is adsorbed onto the column, as a band, which is normally visually determined under ultraviolet (UV) light. Immunodiagnostic procedures take the form either of immunoaffinity columns or of solid-phase ELISA methods. Immunoaffinity columns are used to effect the sample clean-up before the mycotoxin is quantified, either by adsorption onto a Florisil 'tip' or by elution into a simple fluorimeter.

Solid-phase ELISA methods have been developed where the mycotoxin antibody is immobilized, for example, onto a card (about the size of a credit card), a plastic cup (the 'immunodot' approach) or a plastic probe. The presence of the mycotoxin, above a

predetermined level, is indicated by a visually observed colour change within small indentations within the card, cup or probe.

Chromatography of Selected Mycotoxins

The methods used for the chromatographic analysis of mycotoxins will now be further illustrated by describing the determination of the 'important' mycotoxins listed in Table 1. In each case, 'official' methods that have been approved by an appropriate internationally recognized body will be described, together with a selection of recently developed procedures.

Aflatoxins

The chromatographic methods employed for the determination of the aflatoxins ($B_1, B_2, G_1, G_2, M_1, M_2$) include TLC, HPTLC and HPLC, usually in combination with fluorescence detection. The aflatoxins exhibit an intense fluorescence when subjected to UV irradiation.

For TLC and HPTLC the intensity of fluorescence may be estimated either visually (using, for example, the 'comparison of standards' procedure) or densitometrically.

When HPLC methods are employed, the intensity of the fluorescence and the position of the excitation/emission maxima vary with the composition of the mobile phase. For example, the aflatoxins B_1 and G_1 are much less intense than aflatoxins B_2 and G_2 in aqueous or alcoholic solutions. The fluorescence excitation maximum for B_1 occurs at 355 and 363 nm in acetonitrile and water, respectively, whereas the emission maximum varies from 415 (in chloroform) to 450 nm (in water). In aqueous solutions, the sensitivity of the fluorescence detection system may be enhanced by the pre-column treatment of the aflatoxins B_1 and G_1 with trifluoroacetic acid (TFA), or by post-column treatment with either iodine or bromine solutions.

HPTLC, involving semiautomated sample application and fluorescence densitometry, is sufficiently robust to have been successfully exploited in laboratories in developing countries.

Official methods Those methods that have been approved by the AOAC and other international bodies are described in Table 3. Methods 968.22 and 971.24 have also been adopted by the International Union of Pure and Applied Chemistry (IUPAC); methods 975.36 and 972.26 by the American Association of Cereal Chemists (AACC); and methods 970.45 and 971.24 by the American Oil Chemists Society (AOCS). It is evident from Table 3 that many

of the official methods are based upon analytical procedures that were developed many years ago, using a combination of silica gel column chromatography clean-up and normal phase silica gel TLC.

Recent developments Reversed-phase HPLC, with post-column derivatization and fluorescence detection, is now widely used in the developed world for the analysis of the aflatoxins. Post-column iodination is performed within a heated reaction coil, where the column eluent is mixed with iodine-saturated water. Post-column bromination can be performed where bromide ion in the mobile phase is converted to bromine using a commercially available electrochemical cell. Sample clean-up is frequently performed using proprietary immunoaffinity or SPE columns. The AOAC Official Method 991.31, for example, utilizes the Aflatest immunoaffinity column in combination with reversed-phase C_{18} HPLC for the determination of the aflatoxins. A similar approach was reported in 1995 for the determination of aflatoxin M_1 in cheeses. Briefly, the dichloromethane extract is evaporated to dryness in a rotary evaporator, redissolved in a mixture of methanol/water/hexane (1 : 30 : 50 v/v), and subjected to liquid partitioning. The aqueous phases are then cleaned up using an immunoaffinity column containing monoclonal antibodies against aflatoxin M_1 .

Reversed-phase (C_{18}) HPLC quantification, in combination with fluorescence detection, affords an approximately 75% recovery of aflatoxin M_1 , and a limit of quantification of $0.02 \mu\text{g kg}^{-1}$. The fluorimetric excitation and emission wavelengths are 360 and 435 nm. In the EC method (92/95/EEC), the sample clean-up is performed using a combination of FlorisilTM and C_{18} SPE columns. The combination of C_{18} SPE column clean-up and HPLC quantification, with fluorescence detection, is frequently used for the determination of the aflatoxins in a variety of substrates.

HPTLC, in combination with phenyl bonded phase SPE and fluorescence densitometry, has been successfully applied to the determination of aflatoxins in a variety of commodities including corn, cottonseed, sorghum, peanut butter and palm kernels. Typically, aluminium-backed silica gel HPTLC plates are subjected to bidirectional chromatography using anhydrous diethyl ether and chloroform/xylene/acetone (6 : 3 : 1 v/v) in the first and second directions, respectively. Interfering components may be removed by carefully cutting away the upper part of the plate after the first development, before rotating the plate through 180° prior to the second development. The estimation of aflatoxin B_1 , by bidirectional HPTLC, in a variety of commodities is illustrated in Table 4. HPTLC has also been recently used for the

determination of aflatoxin M₁ in milk. The samples were extracted with chloroform contained within a hydrated dialysis tube, before subjecting the concentrated extract to HPTLC on silica gel plates. This method gave a recovery of 96% and fluorescence densitometry gave a detection limit of 0.002 $\mu\text{g L}^{-1}$.

The excitation wavelength was 350 nm, with an emission cut-off of below 400 nm.

A recently reported novel approach to the determination of aflatoxins in corn utilizes silica or immunoaffinity column clean-up in combination with capillary electrophoresis, with laser-induced

fluorescence detection. The reported limit of detection is 0.5 µg kg⁻¹ aflatoxin B₁, with an average recovery of 85% over the range 1 to 50 µg kg⁻¹.

Ochratoxins

Official methods Official AOAC methods exist for the determination of the ochratoxin A in barley, corn and green coffee. These procedures are summarized in Table 5. It is evident from Table 5 that both the TLC methods are rather old, whereas the HPLC procedure is reasonably modern. Each of the official methods utilizes the native fluorescence of ochratoxin A for detection purposes. On a silica gel TLC plate, ochratoxin A fluoresces most intensely under 365 nm UV light. If the plate is sprayed with alcoholic NaHCO₃ solution the fluorescence increases in intensity, and changes from greenish blue to blue in colour. If the TLC plate is quantified densitometrically, the optimum excitation and emission wavelengths are 310–340 and 440–475 nm, respectively. When employing HPLC, the recommended fluorescence detection wavelengths are 333 (excitation) and 460 nm (emission).

The AOAC Method 991.44 has been subjected to an interlaboratory study involving 12 European

laboratories, under the auspices of the AOAC/IUPAC/NMKL (Nordic Committee on Food Analysis). The results of the intercomparison are given in Table 6 for contamination levels, in wheat bran, rye and barley, of between 2 and 9 µg kg⁻¹ ochratoxin A. The mean recoveries varied from 64 to 72%. The method has been accepted as an official NMKL procedure.

Recent developments Recently developed HPLC methods for the determination of ochratoxin A employ silica gel SPE and immunoaffinity clean-up followed by reversed-phase C₈, C₁₈ and C₂₂ HPLC columns, in combination with fluorescence detection. The ionization of the phenolic group in the underivatized toxin is suppressed by the presence of phosphoric or acetic acids in the mobile phase.

An HPLC method (Method 1, Table 7) for the determination of ochratoxin A in roast and ground coffee uses a combination of silica gel SPE and immunoaffinity clean-up in order to ensure a good recovery (87%) of toxin. (Very low recoveries were obtained when immunoaffinity clean-up alone was used.) Fluorescence detection with excitation and emission wavelengths of 333 and 470 nm

Table 6 Interlaboratory study of the official NMKL HPLC method for the analysis of ochratoxin A

Commodity	Coefficient of variation (%)	
	Intralaboratory	Interlaboratory
Wheat bran	21	23–28
Rye	17	20–28
Barley	12	18–31

was employed. The presence of ochratoxin A was confirmed by the HPLC determination of its methyl ester.

HPLC quantification has also been used to determine the ochratoxin A content of milk (Method 2, Table 7). The emulsion produced during the chloroform/methanol extraction was broken by refrigerated centrifugation. After clean-up, the purified extract was dissolved in methanol, by ultrasonic treatment, before application to the HPLC column. The emission and excitation wavelengths of the fluorescence detector were set at 330 and 460 nm. The presence of ochratoxin A, in the range 0.01 to 0.03 $\mu\text{g L}^{-1}$, was confirmed by ELISA.

An HPTLC method (Method 3, Table 7) has recently been developed for the determination of ochratoxin A in parboiled rice. Extraction was performed with chloroform and phosphoric acid; the clean-up involved a combination of partitioning into sodium bicarbonate solution and phenyl

bonded-phase SPE. Bidirectional HPTLC using aluminium-backed silica gel plates was employed, using diethyl ether/methanol (98:2 v/v) and toluene/ethyl acetate/formic acid (5:4:1 v/v) in the first and second directions, respectively. After removing the bottom portion of the plate, a third development was performed, in the same direction, with *n*-hexane/ethyl acetate/acetic acid (18:3:1 v/v). Fluorodensitometric detection (excitation at 365 nm) afforded a mean intralaboratory precision of 5.4% over the concentration range 10 to 200 $\mu\text{g kg}^{-1}$ ochratoxin A. The mean recovery and limit of detection were 83% and 11.6 $\mu\text{g kg}^{-1}$, respectively.

Two intercomparison studies have recently been performed, within the European Commission, Measurements and Testing Programme, on the HPLC determination of ochratoxin A. The first study, using kidney naturally contaminated at 10 $\mu\text{g kg}^{-1}$ ochratoxin A, involved 20 European laboratories. A variety of extraction and clean-up procedures were used, and recoveries ranged from 43 to 128%. The second study, involving 26 European laboratories, used wheat naturally contaminated with approximately 7 $\mu\text{g kg}^{-1}$ ochratoxin A. Again, a variety of extraction and clean-up procedures were employed. Some laboratories compared their normal clean-up method with the use of immunoaffinity columns supplied from two different sources. The recoveries and interlaboratory precision obtained using the normal and immunoaffinity clean-up methods are compared

Table 8 Intercomparison of clean-up methods used for the HPLC determination of ochratoxin A in wheat

Clean-up method	Coefficient of variation (%) (Interlaboratory)	Recovery (%)
Normal	34	58–114
Immunoaffinity (first source)	34	58–114
Immunoaffinity (second source)	42	4–86

in Table 8. A recovery within the range 70 to 110% was considered to be acceptable. The interlaboratory coefficient of variation obtained using normal (and one immunoaffinity) clean-up methods were similar to, but slightly greater than, the values obtained by the intercomparison study of the official AOAC/IUPAC/NMKL procedure.

Deoxynivalenol

Official methods The two official AOAC methods for the determination of deoxynivalenol in wheat both date from 1986; these are outlined in Table 9. The TLC procedure (Method 986.17) involves extraction with acetonitrile/water followed by clean-up using a small column packed with a mixture of charcoal, alumina and Celite. The deoxynivalenol is observed as a blue fluorescent spot, under UV light, on the heated, aluminium chloride-treated plate. When subjected to a collaborative study the reported average recoveries were between 78 and 96%, with intra- and interlaboratory precisions (CV%) of 30–64 and 33–87% respectively.

The GC method includes extraction with water/chloroform/methanol, a silica gel column clean-up (under centrifugation) and derivatization with heptafluorobutyric acid anhydride (HFBA). Chromatography is performed on a 3% OV-101 column (using argon methane as the carrier gas) with a ^{63}Ni electron capture detector. A collaborative study of this procedure afforded an average recovery of 92% and intra- and interlaboratory precisions

(CV%) of 31 and 47%, respectively, for naturally contaminated samples.

Recent developments In 1992, an intercomparison study was reported on the determination of deoxynivalenol in wheat and corn flours. Fifteen laboratories participated, using one- and two-dimensional TLC (five participants), GC (four) and HPLC (six) procedures. Ten of the laboratories used a charcoal-based clean-up method. A mixture of acetonitrile/water was widely used as an extraction solvent. HPLC quantification was performed using UV detection at 225 nm, whereas the GC determinations employed trimethylsilyl, trifluoroacetyl and heptafluorobutyryl derivatives. For all methods the recoveries varied between 68 and 116% for wheat and 53 and 100% for corn. There was no discernible difference in the efficacy of the various quantification procedures.

Typically, TLC methods for the analysis of trichothecenes involve extraction with acetonitrile or methanol followed by clean-up using liquid partitioning and column chromatography on silica gel or Florisil. Deoxynivalenol may be visualized on the TLC plate by spraying with, for example, aluminium chloride, 4-(*p*-nitrobenzyl)-pyridine, *p*-anisaldehyde or cerium sulfate.

Recently developed methods for the determination of deoxynivalenol, T-2 toxin (and zearalenone) are summarized in Table 10.

The HPLC analysis of trichothecenes is frequently performed using gradients of methanol/water or acetonitrile/water in conjunction with C_{18} (or occasionally C_8) columns and detection by UV absorption. Electrochemical detection has also been employed, together with a variety of derivatization techniques. The extraction/clean-up step in the HPLC procedure (Method 1) includes the precipitation of milk protein, with acetic acid, pH adjustment to 7–8, ExtrelutTM column chromatography and a charcoal-alumina clean-up column. The recovery, for the concentration range 25–200 $\mu\text{g L}^{-1}$ deoxynivalenol, was low (57%)

but consistent; the extensive clean-up probably contributed to the loss of toxin.

GC is widely employed for the determination of trichothecenes, including deoxynivalenol, notwithstanding the inconvenience of lengthy clean-up and derivatization steps prior to quantification. Typically, either the original trichothecene, or the alcohol produced by alkaline hydrolysis, is determined. The hydroxyl group(s) of trichothecenes are normally derivatized in order to attain the required volatility and sensitivity. Trimethylsilyl (TMS) derivatives are frequently utilized for the GC of trichothecenes; heptafluorobutyl and pentafluoropropionyl derivatives are employed for electron capture detection (ECD) whereas trifluoroacetates are utilized for flame ionization (FID), ECD and mass spectrometric (MS) detection. GCMS methods have the advantage of high sensitivity together with the opportunity of using mass spectrometry for confirmation purposes. The specificity of MS detection affords the reliable detection of toxins in grains, biological fluids and other matrices. Generally, capillary GC is preferred to the use of packed columns since the efficiency

of the latter can be compromised by interferences. Capillary GC has been used for the analysis of trichothecenes in a variety of commodities.

Both GC/matrix isolation (MI)/Fourier transform infrared (FTIR) spectroscopy and GCMS have been used to analyse mixtures of trichothecenes in a variety of commodities (Method 2, Table 10). Matrix isolation was performed by adding argon to the carrier gas and trapping the effluent on the outer ring of a slowly rotating gold disc, at low temperatures. The IR-transparent argon matrix, containing the isolated trichothecenes, was then analysed by IR spectroscopy, and the presence of individual toxins confirmed by observing the characteristic MI/FTIR bands. Negative ion chemical ionization (NICI) mass spectrometry was used to quantify the high levels (67–445 mg kg^{-1}) of deoxynivalenol found in naturally contaminated sweet corn. Seven *Fusarium* mycotoxins (including deoxynivalenol, T-2 toxin and zearalenone) in barley and maize have also been determined by GC/electron impact-selective ion monitoring MS (Method 3, Table 10). 5 α -Cholestane was used as an internal

standard. The mean recovery for the seven mycotoxins was 92%.

T-2 Toxin

Official methods There are no official AOAC methods for the determination of T-2 toxin.

Recent developments Methods available for the determination of T-2 toxin include TLC, GC and HPLC.

T-2 toxin and other type A trichothecenes (characterized by a hydrogen atom or an hydroxyl group at the C8 position) are visualized on TLC plates by treatment with sulfuric acid or chromotropic acid (disodium 4,5-dihydroxynaphthalene-2,7-disulfonate dihydrate). Another approach involves the formation of the diphenylindenone sulfonyl (Dis) esters of trichothecenes and their visualization, as fluorescent spots under UV light, by spraying the TLC plate with sodium methoxide. Using this procedure 20–25 ng per spot of T-2 toxin can be detected.

The HPLC determination of T-2 toxin is compromised by the lack of the enone chromophore possessed by deoxynivalenol. The successful HPLC determination of T-2 and other Type A trichothecenes requires effective clean-up and derivatization procedures. A variety of post-column derivatization methods have been developed including those involving the UV detection of *p*-nitrobenzoate and diphenylindenone sulfonyl esters of T-2 toxin; the reported detection limits are approximately 10 and 30 ng T-2, respectively.

The capillary GC-ECD determination of T-2 toxin, and other Type A trichothecenes, afford detection limits of about 200 $\mu\text{g kg}^{-1}$ (with one chromatographic clean-up) and 50–100 $\mu\text{g kg}^{-1}$ (with two chromatographic clean-ups). A similar result has been reported using a capillary GC-FID method. T-2 toxin has also been detected in spiked wheat (in combination with deoxynivalenol), at levels of 1 $\mu\text{g kg}^{-1}$, by using a GC-NICI MS-MS method. A highly sensitive

method for T-2 in urine employs capillary GCMS (EI and NICI) with a detection limit of 2–5 $\mu\text{g L}^{-1}$. Capillary GC-PICI MS was employed after clean-up of an acetonitrile extract on an XAD-2 column and derivatization with TFA.

Recently developed GC/NICI/MS and GC/EI/MS methods for the determination of T-2 toxin, and other trichothecenes, are outlined in Table 10 (Methods 2 and 3).

Zearalenone

Official methods There are two official AOAC methods (TLC and HPLC) for the determination of zearalenone in corn (Table 11). The TLC method (976.22) dates from 1976 and has also been adopted by the AACC. The HPLC method (985.18) dates from 1985 and can also be used for the determination of α -zearalenol. No limits of detection are given for these procedures.

The official TLC method for zearalenone involves extraction with chloroform/water, clean-up by silica gel column chromatography and liquid partitioning followed by TLC using either ethanol/chloroform or acetic acid/benzene. Zearalenone fluoresces greenish-blue under 254 nm UV light; and blue under 365 nm UV light after treatment with aluminium chloride.

The official HPLC method for zearalenone and α -zearalenol involves extraction with chloroform/water (in the presence of diatomaceous earth), clean-up by liquid partitioning and chromatography on a C₁₈ column using water/acetonitrile/methanol as the mobile phase. Fluorescence detection is employed.

Recent developments A variety of HPLC methods have been developed for the analysis of zearalenone in corn together with methods for milk, blood, urine and animal tissue. Clean-up procedures include liquid partitioning and the use of silica gel cartridges. The mobile phases used for reversed-phase HPLC include

acetonitrile/water, acetonitrile/water/acetic acid, methanol/acetonitrile/water and methanol/water. Water-saturated dichloromethane containing 2% 1-propanol has been used for normal-phase HPLC. Fluorescence detection is most commonly used; other methods include electrochemical, voltametric and UV spectroscopic detection.

An HPTLC method (Method 4, Table 10) for the determination of zearalenone in maize has recently been developed, based upon the AOAC HPLC procedure (985.15). The mean recovery is 75.3%, over the range 10 to 320 $\mu\text{g kg}^{-1}$ zearalenone.

Most of the numerous GC methods for the determination of zearalenone (and zearalenol) utilize trimethylsilyl derivatization. A recently developed GC method for the determination of zearalenone and other *Fusarium* toxins, in barley and corn, is shown in Table 10 (Method 3).

Fumonisin

Official methods An HPLC method has received Official First Action status from the AOAC International (Table 12). The procedure uses methanol/

water (3 : 1 v/v) as the extraction solvent followed by strong ion exchange (SAX) clean-up and pre-column derivatization with *o*-phthalaldehyde (OPA). The mobile phase is sodium dihydrogen phosphate solution (buffered to pH 3.3)/methanol and fluorescence detection is employed.

Recent developments Typically, the fumonisins are determined by TLC, HPLC or GCMS, using ion exchange SPE clean-up and quantification, after derivatization of the primary amino group. HPLC is by far the most widely used quantification method. A worldwide survey of methods used for the analysis of the fumonisins was reported in 1996. Of the 32 laboratories included, 91% used HPLC. TLC and GC/MS methods were each used by 3% of the laboratories. (ELISA was utilized by the remaining 3%.)

HPLC methods that are broadly similar to the AOAC Official First Action method have also been developed using other clean-up procedures (e.g. C₁₈ SPE and immunoaffinity columns) and mobile phases. The latter include mixtures of acetonitrile/methanol/acetic acid; acidified methanol; and sodium

- (10) Dawlatana M, Coker RD, Nagler MJ and Blunden G (1995). A normal phase HPTLC method for the quantitative determination of fumonisin B₁ in rice. *Chromatographia* 41: 187–190.

hydrogen phosphate solution/methanol followed by acetonitrile/water. Although OPA is used as the derivatization reagent by the majority of laboratories, other reagents have been employed including naphthalendialdehyde, fluoronitrobenzofurazan and fluoescamine. The last reagent is unsatisfactory as it generates two peaks in the HPLC chromatogram for fumonisin B₁.

Three recently developed methods for the determination of the fumonisins in corn-based commodities are outlined in Table 13. Method 1 uses a combination of SAX and C₁₈ SPE clean-up prior to ion-pair HPLC and fluorescence detection; on-line derivatization within a reaction coil is employed. The recovery of the fumonisins ranged from 54 to 110% at 40 and 80 µg kg⁻¹, respectively. Method 2 is an automated procedure using on-line immunoaffinity clean-up, reversed-phase HPLC and electrospray ionization MS detection. The protonated molecule signal (*m/z* 722) was used to achieve a limit of quantification of 250 pg.

An HPTLC method (Method 3, Table 13), for the determination of fumonisin B₁ in rice, has recently been reported. A novel derivatization step involved the brief immersion of the HPTLC plate in a 0.16% acidic solution of *p*-anisaldehyde, followed by quantification by scanning fluorodensitometry. The response was linear over the range 0 to 5 mg kg⁻¹ (ppm).

An intercomparison study on a variety of methods for the determination of the fumonisins in maize has recently been undertaken under the auspices of the European Commission, Measurements and Testing Programme. Twenty-four laboratories participated, using their normal routine procedure for the determination of fumonisins B₁ and B₂ in the range 0.5–3.0 and 0.2–1.5 mg kg⁻¹ (ppm), respectively. All laboratories used a similar method involving extraction with methanol/water, clean-up with an SAX SPE column and HPLC fluorescence quantification of the OPA derivative. The intra- and interlaboratory precisions were high (10 and 11%, respectively, for fumonisin B₁; and 11 and 13%, respectively, for fumonisin B₂). However, the recoveries were low (70 ± 14% and 69 ± 16% for fumonisins B₁ and B₂, respectively). Interestingly, higher recoveries were

associated with extraction by shaking (85 ± 12% for fumonisin B₁) rather than by blending (62 ± 6%).

Conclusions

The continued use of a variety of chromatographic procedures for the determination of mycotoxins is envisaged. Although HPLC is the method of choice in the developed world for a wide range of applications, it is important that precise and accurate methods continue to be developed that are appropriate to the special needs of developing country laboratories.

The aflatoxins are toxic and carcinogenic metabolites of the moulds *Aspergillus flavus* and *A. parasiticus*.

They are often found as contaminants of peanuts, tree nuts, corn and cottonseed. They were discovered as a result of investigations into Turkey X disease in Britain, in which 100 000 turkeys and numerous other poultry died as a result of feeding on peanut meal which had been contaminated with mould.

Thin-layer chromatography (TLC) played a crucial part in the discovery and subsequent research on the aflatoxins and continues to play an important part in the analytical methods used for control of aflatoxins in food and feeds. The four major compounds are aflatoxins B₁, B₂, G₁ and G₂. Aflatoxins B₁ and B₂ have bright blue fluorescence on TLC and G₁ and G₂ are bright green-blue. Aflatoxin B₁ is found in the largest amounts in samples and is also the most toxic and carcinogenic of the four. Aflatoxin M₁ is found in the milk of animals which have ingested aflatoxin B₁.

For the structures of the aflatoxins see Figure 1. After the discovery of the aflatoxins other mycotoxins were discovered and methods of analysis using TLC have been devised for them.

Preparation of Samples

Aflatoxin contamination of food and feeds is usually in the range of ng g⁻¹ to µg g⁻¹. Sampling error is a severe problem in aflatoxin determination because only a few affected kernels can contaminate a large amount of finished product. Amounts as high as 207 000 ng g⁻¹ have been found in individual corn kernels. This is sufficient aflatoxin to produce

a level of contamination of 20 ng g⁻¹ in a batch of 10 000 kernels of grain. Sampling plans have been developed for various commodities. In general, the larger the unit size of the commodity, the larger the sample size should be. The sample should be finely ground and mixed before taking out the analytical test portion. Often the sampling error is larger than the analytical error.

Various methods of analysis have been devised. Many of these have been published in the *Official Methods of Analysis of AOAC International*, after collaborative studies by several laboratories. If the precision and accuracy of the results are acceptable the method becomes official.

The three most widely used extraction and clean-up methods for preparing aflatoxin extracts for TLC are the CB method, the BF method and the immunoaffinity column method. The CB method, named after the Contaminants Branch of the US Food and Drug Administration (FDA), uses chloroform extraction, filtering through paper, addition to a silica gel column, washing with hexane and ether, elution with chloroform-methanol (97:3 v/v), and evaporation to dryness to prepare the extract for TLC. The BF method, named after the Best Foods Company, uses methanol-water (55:45 v/v) extraction, hexane

Figure 1 Structures of aflatoxins B₁, B₂, G₁, G₂ and M₁.

defatting in a separatory funnel, partition into chloroform and evaporation to dryness to prepare the extract for TLC. The immunoaffinity column method uses methanol–water (7 : 3 v/v) for extraction, filtering through paper, dilution with water, filtering through a glass microfibre filter, application to a column upon which antibodies to aflatoxins have been bound, washing with water, elution with methanol and evaporation to dryness to prepare the extract for TLC.

The advantage of the CB method is that it is precise and accurate when correctly performed. Disadvantages include the acquisition and disposal costs of the reagents used. The advantage of the BF method is that it has the lowest cost of any of the methods. The disadvantage is that it results in a somewhat dirtier extract. The advantages of the immunoaffinity column method are its simplicity of performance and the purity of the aflatoxins in the extract. Its disadvantage is the high cost of the columns.

After evaporation, in all three methods, the extract is carefully transferred using rinses of chloroform to a small vial. The solvent is again evaporated to dryness in a water bath under a stream of nitrogen. The residue is dissolved in a small amount of solvent (200 μL), usually benzene–acetonitrile (98 : 2 v/v), for spotting on TLC. Since the use of benzene is sometimes prohibited because of its toxicity, other solvents such as toluene–acetonitrile (9 : 1 v/v) may be used as well.

Aflatoxin Standards

A large source of error in the analysis is due to incorrectly prepared aflatoxin standards. In a check sample series, standards were found that contained more or less than the stated amount of aflatoxins when compared with a correctly prepared standard sent out with the study. It is very important to work with pure and accurate standards if accurate quantitative and qualitative results are to be obtained. Aflatoxin standards may be purchased from chemical distributors but need to be checked by means of TLC or liquid chromatography (LC) to ensure that they are pure. Small quantities of aflatoxin standards are sometimes available from organizations such as the FDA without cost.

Crystalline aflatoxin standards should be handled in a glove box because of their carcinogenicity and the electrostatic nature of the crystals. Because of the difficulty in handling the crystalline material, the aflatoxins are often received as dry films deposited in a precise amount in the bottom of a glass vial. The contents of the vial should be dissolved in the solvent (benzene–acetonitrile, 98 : 2 v/v) and mixed on a vor-

tex mixer for 1 min since the standards do not dissolve rapidly. After mixing, the solution is transferred to a screw-cap vial and the ultraviolet spectra measured between 370 and 330 nm. The concentration can then be calculated using the values listed in the AOAC International Official Method 971.22. The standards are applied to a TLC plate to verify the purity. The solutions must be stored in a closed and sealed vial in a refrigerator at 4–8°C. Mixtures of the four major aflatoxins can be prepared by diluting the concentrated stock solutions. The mixture most often used contains aflatoxins B_1 and G_1 at 1.0 $\mu\text{g mL}^{-1}$ and B_2 and G_2 at 0.2 $\mu\text{g mL}^{-1}$. This ratio between the four aflatoxins approximates to the ratio found in some sample extracts. The aflatoxins in benzene–acetonitrile (98 : 2 v/v) are stable when stored in a closed and sealed vial in a refrigerator at 4–8°C. Evaporation or decomposition of the aflatoxins can be detected using TLC or LC, shown by additional spots or additional peaks or an increase or decrease in the fluorescent intensity, as evidenced by unusual area integration values from the LC detector or TLC densitometer.

Spotting, Development and Examination of the TLC Plate

The plates most often used for aflatoxin analyses are 20 \times 20 cm glass plates, pre-coated with a 0.25 mm layer of silica gel 60 (E. Merck, Darmstadt); plates from other manufacturers may work equally well. Spotting should be done in subdued incandescent light to avoid photodecomposition of the aflatoxins. Using a 10 μL syringe, on an imaginary line 4 cm from the bottom of the plate and 1 cm apart, 2, 5 and two 10 μL spots of the sample extract are applied together with 2, 5 and 10 μL spots of mixed aflatoxin standards; 5 μL of the standard is applied on top of one of the 10 μL spots of sample extract. It is possible to spot four samples on to each plate.

The plate is developed for less than 90 min with acetone–chloroform (1 : 9 v/v) until solvent is within 4 cm of the top of the plate. It may be necessary to adjust the acetone–chloroform ratio to obtain optimum resolution. The plate is removed from the tank and air-dried in the hood in the dark.

Plates are examined under long wave ultraviolet light at 365 nm in a cabinet equipped with a filter for protecting the eyes from the ultraviolet light. Aflatoxins appear in order of decreasing R_F : B_1 , B_2 , G_1 and G_2 . G_1 and G_2 are slightly greener than the blue B_1 and B_2 . The R_F values for the aflatoxins in the sample spots should be the same as those of the standard spots. The aflatoxins in the sample spot upon which the standard is superimposed should

coincide exactly with the standard spots. The intensity of the fluorescence of each of the sample spots may be compared with that of the standard spots to estimate the amount of aflatoxin present in the extract. Separate estimates need to be made for B₁, B₂, G₁ and G₂. If the spots of the smallest portion of the sample are more fluorescent than the strongest standard spot it is necessary to dilute the sample extract and re-chromatograph. The plate may be run on a densitometer equipped with an ultraviolet light source set at 365 nm and an ultraviolet filter before the photomultiplier detector. Connecting the TLC densitometer to a computer permits the integration, calculation, printing, and storage of results. If more accurate quantitative results are necessary, the extract can be re-diluted to a concentration approximately equal to that of the standard and re-chromatographed in the same manner as above. The concentration of each aflatoxin in the extract can be calculated using the formula:

$$\text{ng g}^{-1} = (S \times Y \times V)/(X \times W)$$

where $S = \mu\text{L}$ of standard spot equal to sample; $Y = \text{concentration of standard in ng } \mu\text{L}^{-1}$; $V = \mu\text{L}$ of final dilution of sample extract; $X = \mu\text{L}$ of sample spot equal to standard; and $W = \text{grams of sample that the extract represents}$.

Not all blue fluorescent spots in the extracts are necessarily aflatoxins. Sample extracts may contain interferences, especially at the R_F values of G₁ and G₂. Respotting with an alternative solvent system such as the top phase benzene-ethyl alcohol-water (46 : 35 : 19 v/v) or with benzene-methanol-acetic acid (90 : 5 : 5 v/v) often resolves the aflatoxins from the interferences. Other solvents which are sometimes used are: ether-methanol-water (96 : 3 : 1 v/v), chloroform-acetone-water (88 : 12 : 1.5 v/v), or chloroform-acetone-isopropanol-water (88 : 12 : 1.5 : 1 v/v).

Two-Dimensional TLC

Another powerful technique for resolving the aflatoxins from interferences is two-dimensional TLC. In this technique two spots of aflatoxin standards and one spot of sample extract are spotted on the plate, as shown in Figure 2. The plate is first developed with ethyl ether-methanol-water (96 : 3 : 1 v/v) in the first direction. After development and air drying, the plate is redeveloped in the second direction with acetone-chloroform (1 : 9 v/v). After development and air drying the plate is examined under ultraviolet light at 365 nm for aflatoxin spots. A blue spot should appear at the intersection of imaginary lines from the two standard spots. The

Figure 2 Two-dimensional TLC plate for aflatoxin analysis.

two-dimensional technique works well for difficult materials such as eggs and spices.

Confirmation of Identity of Aflatoxins

To confirm the identities of aflatoxins B₁ and G₁ a technique has been devised which uses derivative formation on the TLC plate. The sample extracts and standards are spotted on the origin line of the plate and 1 μL amounts of trifluoroacetic acid are then added to each spot. After reacting for 5 min, the trifluoroacetic acid is removed by blowing air at 35–40°C on the plate for 10 min. The trifluoroacetic acid catalyses the addition of water across the double bond in the terminal furan ring of aflatoxins B₁ and G₁ to form the derivatives called aflatoxin B_{2a} and G_{2a}, which give lower R_F values than the parent compounds. The plate is developed with chloroform-acetone (85 : 15 v/v). Upon examination of the plate under ultraviolet light at 365 nm, sample and standard will have low R_F blue and green spots of the derivatized aflatoxins. Since aflatoxin B₂ and G₂ do not have the unsaturated double bond, they will be unaffected by the test and will appear at their normal R_F values. For additional confirmation the plates can be sprayed with sulfuric acid-water (1 : 3 v/v), which causes the aflatoxin spots to change from blue or blue-green to yellow fluorescence.

Mass Spectrometric Confirmation of the Aflatoxins

The aflatoxins may be confirmed by negative ion chemical ionization-mass spectrometry. The aflatoxin is first purified using preparative TLC. The entire extract is applied along the origin line of a TLC

plate which is developed using chloroform–acetone (9 : 1 v/v). After drying, the silica gel is scraped from a band containing the aflatoxin B₁. If the silica gel is scraped into a sintered glass funnel the aflatoxin can be eluted with chloroform–methanol (2 : 1 v/v). After evaporation and re-dissolving in acetone, the aflatoxin can be introduced into the inlet probe of the mass spectrometer and spectra of sample and standard aflatoxin compared.

Methods of Analysis for Aflatoxin M₁

When cows consume aflatoxin in their feed, a small percentage of it is metabolized and excreted in the milk in the form of aflatoxin M₁. Aflatoxin M₁ is also toxic and carcinogenic, so methods have been developed to detect it in milk. Since infants and children are major consumers of milk products, the levels of concern for M₁ in milk are set quite low by various countries, in the range of 0.05–0.5 µg L⁻¹. Analyses of milk and cheese samples at these low levels are more difficult. One method of analysis uses partition from the milk into chloroform and silica gel column clean-up before the TLC determination. Another method used extraction from the milk on to a C₁₈ solid-phase extraction column and clean-up on a silica gel column before TLC or LC determination. An immunoaffinity column clean-up can also be used.

TLC is accomplished on 10 × 10 cm or 20 × 20 cm, 0.25 mm layer thickness silica gel 60 plates developed with chloroform–acetone–isopropanol (87 : 10 : 3 v/v). Other solvent systems which have been used are ether–methanol–water (95 : 4 : 1 v/v) and ether–hexane–methanol–water (87 : 10 : 4 : 1 v/v).

A two-dimensional TLC method for aflatoxin M₁ has been developed for liver but also works for milk and cheese extracts. The plate is spotted in a similar manner to the two-dimensional plate for aflatoxin B₁ and developed in the first direction with ether–methanol–water (95 : 4 : 1 v/v) and after development and drying is developed in the second direction with chloroform–acetone–isopropanol (87 : 10 : 3 v/v). The developed plate is examined under ultraviolet light at 365 nm for a blue spot at the intersection of imaginary lines from the two standard spots.

The confirmatory technique using trifluoroacetic acid works for aflatoxin M₁ as well but is performed using two-dimensional TLC and requires heating the plate in an oven at 75°C for the reaction to occur.

TLC Determination of Other Mycotoxins

Mycotoxins can be generated by a large number of mould species. Several books review the incidence

and toxicity of the most common mycotoxins. The interest of the regulatory authorities has been focused on relatively few of these metabolites that cause problems in human and animal health. The mycotoxins of regulatory interest are currently the aflatoxins, ochratoxin A, patulin, fumonisins, deoxynivalenol, other trichothecenes and zearalenone. TLC procedures are described below for these mycotoxins.

Ochratoxin A

Ochratoxin A (Figure 3) is a metabolite of some *Aspergillus* and *Penicillium* species. It is found as a contaminant of barley, corn, wheat, oats and coffee. It has also been found in meat, human blood and human milk. Ochratoxin A causes porcine nephropathy, notably in some Scandinavian countries when contaminated barley is fed to swine. Ochratoxin A is extracted from samples with chloroform in the presence of phosphoric acid and cleaned up using partition into sodium bicarbonate and C₁₈ solid-phase extraction. In a similar manner to the TLC of aflatoxin discussed above, ochratoxin A is spotted on a plate pre-coated with a 0.25 mm layer of silica gel 60 (E. Merck, Darmstadt) and developed with benzene–methanol–acetic acid (18 : 1 : 1 v/v) or toluene–ethyl acetate–formic acid (5 : 4 : 1 v/v). After drying, the plate is examined under long and short wave ultraviolet light (365 and 254 nm). Ochratoxin A ($R_F = 0.65$) fluoresces brightest under long wave ultraviolet light and is usually accompanied by the less toxic ochratoxin B ($R_F = 0.5$) which fluoresces brightest under short wave ultraviolet light. The fluorescence of the ochratoxins can be enhanced by spraying the plate with alcoholic sodium bicarbonate solution which changes them to their more fluorescent salt forms. The ochratoxins can be confirmed by ester formation using boron trifluoride in ethanol and re-chromatographing using the same conditions as above. The ethyl esters appear at lower R_F values than the parent compounds under long and short wave ultraviolet light.

Patulin

Patulin (Figure 3) is a lactone metabolite of several moulds, including *Penicillium expansum*, which causes brown rot in apples. Patulin is often found in apple juice, especially juice from fallen apples. Patulin can be extracted from apple juice with ethyl acetate and cleaned up using silica gel column chromatography. After evaporation, the extract is dissolved in chloroform and spotted on silica gel plates and developed with toluene–ethyl acetate–formic acid (5 : 4 : 1 v/v). After drying, the plate is sprayed

Figure 3 Structures of ochratoxin A, patulin, fumonisin B₁, deoxynivalenol, T-2 toxin, diacetoxyscirpenol, satratoxin H and zearalenone.

with 3-methyl-2-benzothiazolinone hydrazone-HCl (MBTH) solution and heated for 15 min in an oven at 130°. Under ultraviolet light at 365 nm, patulin ($R_F = 0.5$) appears as a yellow-brown fluorescent spot. The amount of patulin in the sample can be determined by comparing the intensity of fluorescence of the standard and sample spots. Other TLC developers, such as hexane-anhydrous ether (1 : 3 v/v), chloroform-methanol (95 : 5 v/v), and

chloroform-acetone (9 : 1 v/v) can be used to confirm the identity of the patulin. After development, plates are sprayed with MBTH to reveal the patulin.

Fumonisin

Fumonisin B₁ (Figure 2) and B₂ are metabolites of *Fusarium moniliforme* and *F. proliferatum*. They are common natural contaminants of corn and have

caused deaths in horses and swine. Small amounts have been found in cornmeal and breakfast cereals. In order to ensure that they are not present in food in excessive amounts, methods of analysis have been developed. Most methods use LC after formation of derivatives of the primary amine function with reagents such as *o*-phthalaldehyde. However, a reversed-phase TLC determination has been devised. The fumonisins, dissolved in acetonitrile–water (1 : 1 v/v), are spotted at the origin of a 10 × 10 cm C₁₈ plate and developed with methanol–1% KCl in water (3 : 1 v/v). After drying, the plates are sprayed with 0.1 mol L⁻¹ sodium borate (pH 8–9) followed by fluorescamine (0.4 mg mL⁻¹ in acetonitrile). After a 1 min delay, further spraying with 0.01 mol L⁻¹ boric acid–acetonitrile (2 : 3 v/v) is carried out. Examination under 365 nm ultraviolet light reveals fluorescent yellow spots of fumonisin B₁ ($R_F = 0.5$) and fumonisin B₂ ($R_F = 0.1$).

Deoxynivalenol

Deoxynivalenol (Figure 2), also called vomitoxin, is a trichothecene metabolite of *F. graminearum*, an organism which causes a disease in barley and wheat called head blight or scab. Deoxynivalenol is found as a contaminant of barley, wheat, corn and rye and causes adverse health effects in animals and humans, including feed refusal and vomiting in swine. An advisory level of 1 µg g⁻¹ has been set for finished wheat products. Methods for analysis have been devised using LC and TLC. The TLC method uses acetonitrile–water (84 : 16 v/v) extraction and clean-up using a charcoal–alumina–Celite (7 : 5 : 3 v/v) column. The extracts and standard deoxynivalenol are dissolved in methanol and spotted near the 20 cm edge of a 20 × 10 cm Linear-K High Performance (Whatman, Clifton NJ) or equivalent silica gel plate and developed with chloroform–acetone–2-propanol (8 : 1 : 1 v/v). After drying the plate is sprayed with aluminium chloride solution (20 g AlCl₃·6H₂O in 100 mL methanol–water: 1 : 1 v/v) and then heated in an oven at 120° for 7 min. Under 365 nm ultraviolet light, deoxynivalenol appears as a blue fluorescent spot at $R_F = 0.78$. Spots may be scanned with a densitometer.

Other Trichothecenes

The trichothecenes are a large group of fungal metabolites produced by various species of *Fusarium*, *Myrothecium*, *Stachybotrys*, *Verticimonosporium*, *Cylindrocarpon*, *Trichoderma* and *Tricothecium*. They have been implicated in numerous farm-animal poisonings. A human disease called alimentary toxic

aleukia occurred in the former Soviet Union during World War II when grains were eaten after they had lain out in the field under snow during the winter. *Fusarium* moulds isolated from these grains were shown to produce large amounts of T-2 toxin (Figure 3) and related derivatives. T-2 toxin and related compounds can be analysed by silica gel TLC using chloroform–methanol (9 : 1 v/v) as the developer. Since the trichothecenes are colourless and do not fluoresce, it is necessary to spray the developed plate with sulfuric acid–methanol (1 : 1 v/v), heat for 10 min at 100°C and examine the plate under 365 nm ultraviolet light. Trichothecenes of the T-2 group will appear as blue fluorescent spots, T-2 at $R_F = 0.64$, diacetoxyscirpenol (Figure 3) at $R_F = 0.60$, neosolaniol at $R_F = 0.39$, dihydroxydiacetoxyscirpenol at $R_F = 0.32$ and HT-2 toxin at $R_F = 0.31$.

Other trichothecenes of the nivalenol group do not form fluorescent derivatives with sulfuric acid but instead give a dark pink to brown spot when the plate is examined under visible light. A more useful detection procedure for these compounds is spraying with 4-(*p*-nitrobenzyl)-pyridine (NBP: 1% in chloroform), heating for 30 min at 150°C and spraying with tetraethylenepentamine (TEPA). Under visible light a plate developed with chloroform–methanol (9 : 1 v/v) will have blue spots of fusaranon-X at $R_F = 0.36$, and dihydronivalenol at $R_F = 0.07$. A plate developed with benzene–acetone (1 : 1 v/v) will have tetraacetylnivalenol at $R_F = 0.62$, crotocin at $R_F = 0.59$, dihydronivalenol at $R_F = 0.07$ and nivalenol at $R_F = 0.09$.

Another type of trichothecene is a series of macrocyclic di- and trilactonic derivatives of verrucarol. These have been implicated in a disease of horses and other farm animals called stachybotryotoxicosis. Recently they are suspected of contributing to the death of some infants exposed to the air in mouldy houses. Since they contain an ultraviolet-absorbing functional group, they can be detected by using silica gel plates which fluoresce under 254 nm ultraviolet light. The satratoxins appear as dark spots on a white background. If developed with chloroform–2-propanol (99 : 1 v/v) roridin E will appear at $R_F = 0.85$, verrucarin J at $R_F = 0.45$, satratoxin F at $R_F = 0.40$, satratoxin G at $R_F = 0.20$ and satratoxin H (Figure 3) at $R_F = 0.15$.

Zearalenone

Zearalenone (Figure 3) is a metabolite of the mould *F. graminearum* also called by its perfect name *Gibberella zeae*. Zearalenone is found in barley, wheat and corn and causes hyperoestrogenism in swine, resulting in infertility and spontaneous abortions. It

sometimes co-occurs with deoxynivalenol. Zearalenone can be extracted from grain with chloroform and cleaned up using a silica gel column, followed by defatting by partitioning between hexane and acetonitrile. For TLC the samples and standards are dissolved in benzene and spotted on a silica gel and developed with ethanol–chloroform (5 : 95 v/v) or acetic acid–benzene (5 : 95 v/v). Under 254 nm ultraviolet light, zearalenone appears as a greenish-blue fluorescent spot at $R_F = 0.5$. If the plate is sprayed with an aluminium chloride solution and heated for 5 min at 130°C, zearalenone will appear under 365 nm ultraviolet light as a blue fluorescent spot.

Summary

TLC methods have been developed to analyse for a variety of mycotoxins in the commodities in which they occur. TLC densitometric determinations provide precise quantitative data at ng g^{-1} to $\mu\text{g g}^{-1}$ levels. The major advantages of TLC over LC are its low cost and its use as a screening tool. The commercial availability of precoated TLC plates, including silica gel, reversed-phase and high performance plates has resulted in expanded applications in the mycotoxin field. The role of TLC in the analysis of mycotoxins will continue for the foreseeable future.

AIR LIQUEFACTION: DISTILLATION

R. Agrawal and D. M. Herron, Air Products and Chemicals, Hamilton Boulevard, Allentown, PA, USA

Copyright © 2000 Air Products and Chemicals, Inc

Oxygen, nitrogen and argon, the major components of air, have been separated by distillation at cryogenic temperatures for nearly a century. Air was commercially liquefied as early as 1895 by Carl von Linde and also by William Hampson. Linde separated oxygen from air by distillation in a single column in 1902. A commercial plant producing pure nitrogen was already in operation by 1904. The first double-col-

umn distillation system, the predecessor to current double-column processes, was commissioned in 1910 by Linde. Argon was produced on an industrial scale by 1913. Today the major industrial companies supplying products from air distillation and liquefaction and also the equipment for this purpose are: AGA, Air Liquide, Air Products and Chemicals, the BOC Group, Linde, Messer Group, Nippon Sanso and Praxair.

The composition of dry and impurities-free air is given in Table 1. The critical temperature and normal boiling point (at 101.3 kPa) for each component is also listed. In this table, and in the rest of this chapter, concentration in p.p.m. refers to parts per million on a volume basis. The gases listed in Table 1 are used in

Table 1 Composition of air and thermodynamic properties of its constituent gases

<i>Constituent gas</i>	<i>Concentration (mol%)</i>	<i>Boiling temperature (°C)^a</i>	<i>Critical temperature (°C)</i>
Nitrogen	78.12	− 195.8	− 146.9
Oxygen	20.95	− 182.9	− 118.8
Argon	0.93	− 185.9	− 122.4
Neon	18 p.p.m.	− 246.1	− 228.8
Helium	5.3 p.p.m.	− 268.9	− 267.9
Krypton	1.1 p.p.m.	− 153.4	− 63.8
Xenon	0.08 p.p.m.	− 108.1	− 16.6

^a Boiling temperature at 101.3 kPa.

a wide range of industrial and medical applications. Typical industries using these gases include: ferrous and nonferrous metals, chemicals, petroleum, food, paper, glass, textile and electronics. Oxygen is generally used as an oxidant while nitrogen and argon are used to provide inert atmospheres. Krypton is used in light bulbs, lasers, sputtering of electronic components and high energy physics. Neon is used in fluorescent lighting, infrared detection equipment and experimental physics at cryogenic temperatures. Xenon is used in electronic flashlights, as an anaesthetic and in a new application where an on-board xenon ion propulsion system is used for positioning a satellite. Helium is not generally recovered from air due to its low concentration.

The history of air distillation started with oxygen production followed by recovery of other constituents. Therefore, the distillation processes to produce oxygen are described first here followed by argon and then nitrogen. These topics are followed by liquefaction processes and finally a brief description is given of the major equipment used in cryogenic air separation and liquefaction processes.

Distillation

Distillation of Air to Recover Oxygen

The basic steps of any cryogenic air distillation process are shown in **Figure 1**.

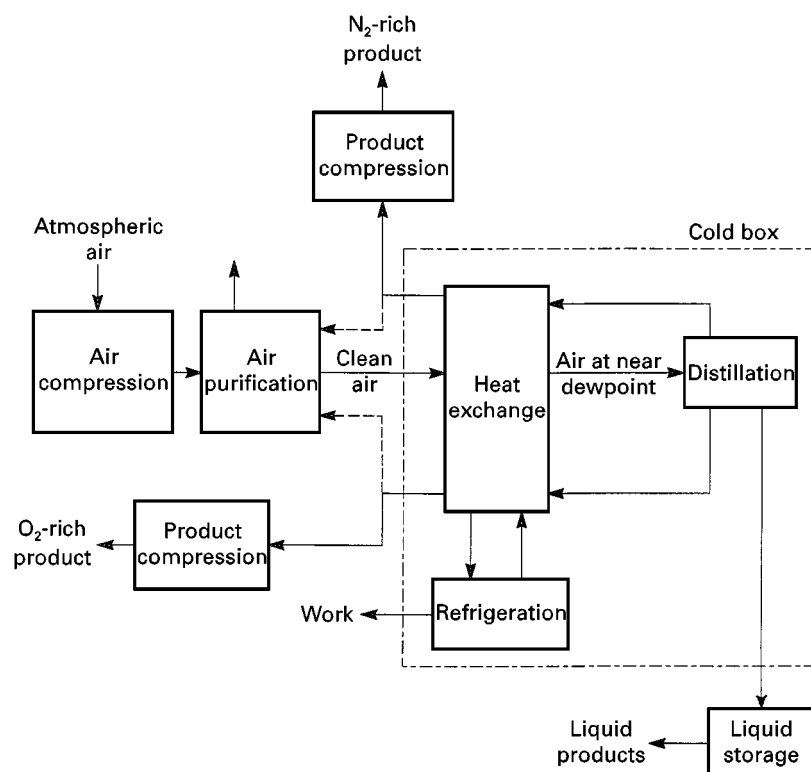

Figure 1 Basic steps in a cryogenic air distillation plant.

Air is first compressed in a multistage compressor and cooled to near ambient temperature. Given the boiling point temperatures of nitrogen and oxygen in Table 1, it is clear that air has to be cooled to extremely low temperatures before it can be distilled. It follows that a number of impurities present in air and which would freeze at such cryogenic temperatures must be removed to avoid plugging of heat exchange and separation equipment. Typical impurities that are not listed in Table 1 but are present in air include: water (after compression air is saturated); carbon dioxide (about 375 p.p.m.); hydrocarbons such as acetylene (0.1–1 p.p.m.), methane (2–10 p.p.m.) and some higher hydrocarbons in varying concentrations (ethylene, propylene, ethane, etc.); carbon monoxide; nitrogen oxides and sulfur compounds. Therefore, in the second step, compressed air is sent through a purification system at least to remove impurities such as water, carbon dioxide, acetylene, nitrogen oxides and sulfur compounds.

In the third step, the compressed and cleaned air is cooled to near its dewpoint by heat exchange. Finally, the cooled air is sent to an appropriate distillation column system. Here air is distilled into at least two product streams – one stream is enriched in oxygen and the other is enriched in nitrogen. Both of these streams are then warmed to near ambient temperature by countercurrent heat exchange with the incoming air. When a product stream is required at a higher pressure, it is further compressed. Liquid products such as liquid oxygen, liquid nitrogen or liquid argon can also be produced from the distillation column system and sent to liquid storage for later distribution.

The heat exchanger and the distillation system are enclosed in a well-insulated enclosure called the cold box. Despite the insulation, there is heat leakage and therefore, refrigeration is provided to the cold box to keep the inside equipment cold. For this purpose, modern cryogenic plants employ turbo-expanders that are also enclosed in the cold box. These turbo-expanders produce work out of the cold box and keep all the equipment at the desired cryogenic temperatures.

Now that the basic steps that are common to all the air distillation plants have been described, attention will be paid to the distillation of air after it is cooled to near its dewpoint temperature. The distillation of air is at the heart of an air separation plant and its arrangement varies with the number, quantity and purity of products being produced.

The early developments in air distillation to produce oxygen were propelled by the invention of the oxyacetylene blow torch for welding and steel cutting. In 1902, Carl von Linde introduced the first air distillation process using a single distillation column.

A simplified sketch of this single column arrangement is shown in Figure 2.

Compressed, cleaned and cooled air that is near its dewpoint temperature is first condensed in a reboiler-condenser located in the bottom (sump) of the distillation column. The condensed liquid air is then reduced in pressure across a valve and fed to the top of the distillation column. The stream provides both the feed and the liquid reflux. From Table 1 it can be seen that, of the three major components in air, nitrogen is the most volatile, oxygen the least volatile and argon is of intermediate volatility. As a result, the liquid descending the distillation column becomes enriched in oxygen. The vapour needed for distillation is provided by boiling the oxygen-enriched liquid in the sump by heat exchange against the condensing air in the reboiler-condenser. A portion of the vapour rising from the sump is collected as gaseous oxygen product while the rest is allowed to travel up the distillation column. As vapour ascends the distillation column, it becomes enriched in nitrogen and finally leaves from the top of the column as a nitrogen-enriched waste stream. If needed, a liquid oxygen product stream is collected from the sump of the distillation column. Even when liquid oxygen is not a desired product, a very small quantity of liquid oxygen is continuously withdrawn from the bottom of the distillation column to avoid accumulation of hydrocarbons in the sump. Both the gaseous oxygen product stream and nitrogen-rich vapour stream are then warmed to near

Figure 2 A single column to produce oxygen.

ambient temperature by heat exchange against the incoming air stream (Figure 1). While the early plants produced oxygen at a purity of 80–90%, the single-column process can provide oxygen at any desired higher purity. Generally, the purity of oxygen used in metal welding and cutting is 99.5% or greater.

The problem with the single distillation column process shown in Figure 2 is that the recovery of oxygen is low. The reason is that the minimum concentration of oxygen in the nitrogen-rich vapour stream leaving the top of the distillation column is limited to that value which is in equilibrium with the liquid air that is fed at the top. Since the concentration of oxygen in air is fairly high, a sizeable fraction of the oxygen in the feed air leaves in the nitrogen-rich vapour stream. To illustrate this for a distillation column operating at 1.4 atm and producing 99.5% oxygen, the pressure of feed air is about 5 atm and a vapour stream in thermodynamic equilibrium with the liquid air stream (at 1.4 atm) will be 6.9% oxygen. A typical oxygen recovery from such a distillation column would only be in the neighbourhood of 14 mol of oxygen per 100 mol of feed air.

It is clear that, for higher recoveries of oxygen, the concentration of oxygen in the nitrogen-rich vapour stream leaving the top of the distillation column must be low. In other words, both product streams should be relatively pure. This requires that the liquid reflux to the top of the distillation column should also be relatively pure. It seems that Georges Claude was the first to provide the solution by using his dephlegmation equipment in 1903. However, it was Carl von Linde's double distillation column of 1910 that revolutionized the industry and is still the workhorse of the modern cryogenic oxygen plants.

A typical double distillation column configuration is shown in Figure 3.

In this arrangement, compressed, cleaned and cooled air is now sent to a high pressure distillation column that operates at about 6 atm. As the vapour rises up this high pressure column, it is enriched in nitrogen and at the top of the column, the concentration of oxygen has been reduced to an extremely low level. The nitrogen vapour is condensed by heat exchange in a reboiler-condenser. Of this condensed nitrogen stream, about 60% is returned back to the top of the high pressure column as liquid reflux; approximately 40% of the flow is sent to the top of a low pressure column that operates at around 1.4 atm. The liquid descending the high pressure column becomes enriched in oxygen to produce crude liquid oxygen leaving the bottom (typically around 35% oxygen). This crude liquid oxygen is reduced in pressure across a valve and fed to an intermediate location in the low pressure column. In the low pres-

Figure 3 A double-column arrangement to produce oxygen.

sure column, crude liquid oxygen is distilled to produce a nitrogen-rich vapour stream at the top and an oxygen product stream at the bottom. The boil-up at the bottom of the low pressure column is provided by vaporizing the liquid oxygen stream in the sump by heat exchange against the condensing nitrogen vapour stream from the top of the high pressure column. A portion of the vapour from the reboiler-condenser is recovered as gaseous oxygen product while the rest rises to perform distillation in the low pressure column. When needed, some liquid oxygen can also be recovered from the sump as product.

In a double-column arrangement, the main purpose of the high pressure column is to distil and provide two saturated liquid streams from the feed air – a liquid nitrogen reflux and a crude liquid oxygen feed. It is in the low pressure column that the crude liquid oxygen is distilled to provide the needed oxygen product stream. The liquid nitrogen stream provides the much needed liquid reflux at the top of the low pressure column. By using sufficient stages of separation in the high pressure column, the concentration of oxygen in the liquid nitrogen stream can

often be reduced to p.p.m. level. Therefore, the concentration of oxygen in the nitrogen-rich vapour stream from the top of the low pressure column is reduced to extremely low levels. This not only allows the potential to recover the nitrogen-rich vapour stream as a useful product stream, but also makes very high recoveries of oxygen possible. For a double-column process, production of 99.5% oxygen in excess of 20.5 mol per 100 mol of feed air (maximum oxygen content being 20.95 mol) is quite common.

For most uses, gaseous oxygen is needed at pressures greater than atmospheric pressure. This pressure can range from about 2 atm absolute pressure for glass-making to pressures in the range of 30–80 atm for the gasification of hydrocarbons such as coal and petroleum residuum. One obvious method to deliver pressurized oxygen is to compress gaseous oxygen to the desired pressure after it exits the cold box. However, safety considerations tend to make the equipment associated with oxygen compressors expensive. In certain applications, where both oxygen and nitrogen are needed at higher pressures, one has the option of increasing the pressure of the distillation columns and directly produce both products at elevated pressures. Unfortunately, the low pressure column is seldom operated at pressures greater than 8 atm absolute. This is because the pressure of the high pressure column is typically greater than two to three times the pressure of the low pressure column and distillation in the high pressure col-

umn must be conducted at a pressure that is sufficiently lower than the critical pressures of nitrogen and oxygen. A third method that is becoming more popular is the use of a pumped liquid oxygen process. This method is also sometimes referred as internal oxygen compression. A schematic of such a plant is shown in Figure 4.

In the pumped liquid oxygen process of Figure 4, air is compressed in a multistage air compressor (MAC) to about 6 atm absolute pressure, cooled to near ambient temperature and then sent to a molecular sieve purifier. About 70% of the cleaned air is directly fed to the cold box for cooling in the main heat exchanger. From an intermediate location of the main heat exchanger, corresponding to 100°C to –130°C, approximately 10–20% of this flow is withdrawn and expanded in a turbo-expander to a pressure slightly above atmospheric pressure and fed to an intermediate location of the low pressure column. The work extracted from the turbo-expander provides the needed refrigeration for the cold box. The air that remains after the withdrawal of expander feed is cooled to near the dewpoint temperature and is fed to the bottom of the high pressure column. The arrangement of the double distillation column process is the same as discussed in Figure 3, with only two differences. The first is that the liquid nitrogen stream from the top of the high pressure column is cooled in a subcooler heat exchanger against the nitrogen-rich vapour streams.

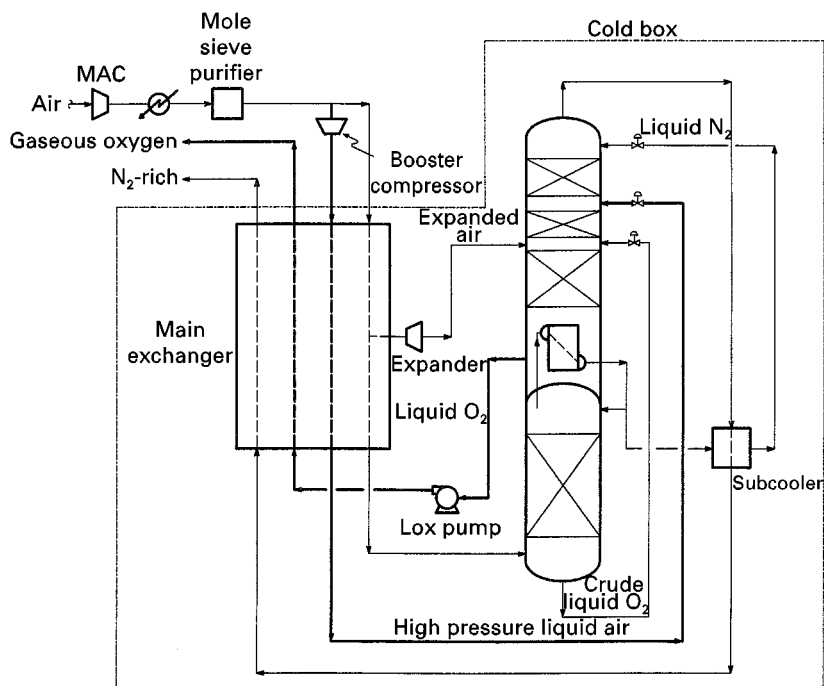

Figure 4 Pumped liquid oxygen flowsheet.

This increases the fraction of liquid in this stream as its pressure is reduced to that of the low pressure column. This technique, which is commonly used in any oxygen plant to increase liquid nitrogen reflux to the low pressure column, has the beneficial effect of increasing the purity and recovery of products.

The second major difference is the withdrawal of oxygen product from the low pressure column as liquid and its subsequent vaporization. The liquid oxygen is pumped in a liquid oxygen pump to the desired oxygen product pressure. This pumped liquid oxygen is then vaporized in the main heat exchanger. In order to maintain refrigeration balance, it is essential that another stream be condensed through heat exchange as the pumped liquid oxygen is being vaporized. For this purpose, about 30% of the cleaned air is further boosted to a higher pressure in a booster compressor. The pressure of the boosted air is chosen such that it would easily condense through heat exchange with the vaporizing oxygen stream. Generally the pressure of the condensing air stream is much greater than the oxygen stream. The condensed liquid air from the main heat exchanger is appropriately fed to either one or both of the distillation columns. The warmed gaseous oxygen stream provides the desired pressurized oxygen product.

While the early oxygen plants produced only a few tons of oxygen per day, modern plants are capable of producing in excess of 3000 tons per day of oxygen in a single train.

Distillation of Air to Recover Argon

After nitrogen and oxygen, argon is the most abundant component in air. Its inert property is quite attractive for metals and several other material-processing applications. Within a very short time of the discovery of the double-column system, argon was distilled from air in 1913. The distillation arrangement to produce argon in modern plants was generally described in a German patent by 1935.

The arrangement for argon production starts with an examination of the argon concentration profile in the low pressure column of a double-column process. From the normal boiling temperatures listed in Table 1, it is readily observed that the volatility of argon is between that of nitrogen and oxygen and, furthermore, it is closer to oxygen than nitrogen. As a result, the concentration of argon in the liquid nitrogen stream from the high pressure column (Figures 3 and 4) is at p.p.m. level and virtually all the argon is contained in the crude liquid oxygen. Therefore, the bulk of the argon in air enters at an intermediate point on the low pressure column. When oxygen containing less than 0.5% argon is produced, argon is forced to escape from the top of the low

pressure column in the nitrogen-rich vapour stream. However, the liquid nitrogen reflux stream is virtually free of argon and tends to drive argon down the low pressure column. Consequently, the concentration of argon in the vapour phase at an intermediate location between the crude LOX feed and the oxygen product withdrawal point reaches levels approaching 20%. A typical vapour-phase argon concentration profile in the low pressure column is shown in Figure 5. The build-up of argon provides an opportunity to withdraw a side vapour stream from near the location where a peak in argon concentration occurs and to distil it further in a side distillation column to produce concentrated argon.

A typical argon recovery arrangement is shown in Figure 6. An argon-rich vapour stream containing between 10 and 25% argon, p.p.m. levels of nitrogen and the rest oxygen is withdrawn from an intermediate location of the bottom section of the low pressure column and is fed to the bottom of a side argon column. The flow of this vapour stream is about 20% of the feed air. As vapour ascends the side argon column, it is depleted in oxygen. The development of structured packing for cryogenic distillation columns has allowed the modern cryogenic plants to use in excess of 175 theoretical stages of separation in the side argon column. As a result, the vapour at the top of this column can contain only p.p.m. levels of oxygen. This vapour stream is condensed in a reboiler-condenser; most of it is returned back as reflux to the side argon column and a small portion is recovered as a crude argon stream. The liquid to vapour flow ratio in this column is in the neighbourhood of 0.97. The liquid from the bottom of the side argon column is

Figure 5 Vapour-phase composition in the low pressure column.

Figure 6 Distillation arrangement for argon separation from air for the process shown in Figure 4.

pumped back to the argon-rich vapour draw location of the low pressure column. Condensation at the top of the side argon column is provided by boiling a portion of the crude liquid oxygen at nearly the low pressure column pressure, as shown in Figure 6. The vaporized crude liquid oxygen stream is fed to the low pressure column a few stages of separation below the location where the unboiled crude liquid oxygen is fed. The recovery of argon from cryogenic air is easily in the range of 70–85% and occasionally, if needed, it can be as high as 95% of the total argon contained in the feed air.

While the concentration of oxygen in the crude argon recovered from the arrangement in Figure 6 is below 5–100 p.p.m., the nitrogen concentration is much higher, as nearly all the nitrogen contained in the argon-rich vapour stream shows up in the crude argon. Generally, the argon product specification requires that the nitrogen concentration also be below 5 p.p.m. Therefore, the crude argon stream is subsequently distilled in a pure argon column with separation stages both below and above the feed. Boil-up and condensing duties for this column are extremely

low and are easily provided by using side streams that are withdrawn from one or more appropriate process streams, shown in Figure 6, such as crude liquid oxygen, high pressure liquid air or high pressure nitrogen vapour. A waste vapour stream containing all the nitrogen is withdrawn from the top of the pure argon column and pure liquid argon product is collected and sent to a storage tank from the bottom of this column.

Distillation of Air to Recover Nitrogen

In most industrial applications, nitrogen is used as an inert gas. Cryogenic air separation can easily produce nitrogen gas with concentrations of oxygen below 5 p.p.m. Until the 1950s, the demand for nitrogen was low. Supply could easily be met by withdrawing a portion of nitrogen vapour from the top of the high pressure column as a co-product of a double-column process for oxygen production (for example, see Figure 6). Generally, up to 30% of the feed air can be recovered as high pressure nitrogen product from the top of the high pressure column. When needed, a portion of the nitrogen-rich vapour stream from the top

of the low pressure column can also be recovered as a useful product.

In the 1960s industrial demand for nitrogen increased, and this led to a need for plants that were designed solely for nitrogen with no co-production of oxygen. For most applications, nitrogen product is required at a pressure between 6 and 10 atm. There are two basic schemes for nitrogen separation from air: one uses a single column while the other uses two columns (similar to the double-column process for oxygen production). The single-column process is used for relatively small size nitrogen plants (up to about 500 tons per day of nitrogen) and two-column processes are used for larger size plants. Cold boxes can now be designed to produce as much as 10 000 tons per day of nitrogen in a single train.

A single-column process for nitrogen separation is shown in **Figure 7**.

Feed air is compressed to a pressure in excess of about 5 atm absolute, cleaned of impurities in the molecular sieve purifier and cooled to near its dew-point in the main heat exchanger by heat exchange against the returning streams. The cooled air stream is then fed to the bottom of a single column. Sufficient separation stages are used in this column to attain the desired purity at the top of this column. A portion of the nitrogen vapour from the top is withdrawn and warmed in the main heat exchanger to provide the desired nitrogen product. The rest of

the nitrogen vapour stream is condensed in a reboiler-condenser and returned as reflux to the column. The ratio of liquid to vapour flow rates in the column is in the neighbourhood of 0.6. The crude liquid oxygen stream from the bottom of the column is reduced in pressure and vaporized in the reboiler-condenser. The vaporized stream is partially warmed in the main heat exchanger and then expanded in a turbo-expander to near atmospheric pressure to provide the needed refrigeration for the plant. The expanded stream is then warmed to near ambient temperature in the main heat exchanger and eventually discharged as an oxygen-rich waste stream. The concentration of oxygen in the waste stream is approximately 35%. The flow rate of the nitrogen product stream is about 40–50 mol per 100 mol of the feed air.

The main problem with the single-column process is that the crude liquid oxygen leaving from the bottom of the column is at best, in thermodynamic equilibrium with the feed air. This means that there is a lower limit to the concentration of nitrogen in the crude liquid oxygen stream. This limits the recovery of nitrogen. For higher recoveries of nitrogen and more efficient processes, it is essential that the crude liquid oxygen stream be further distilled to recover the contained nitrogen. **Figure 8** shows such a two-column process.

The major difference between this process and the single-column process of **Figure 7** is that now

Figure 7 A single distillation column process for nitrogen production.

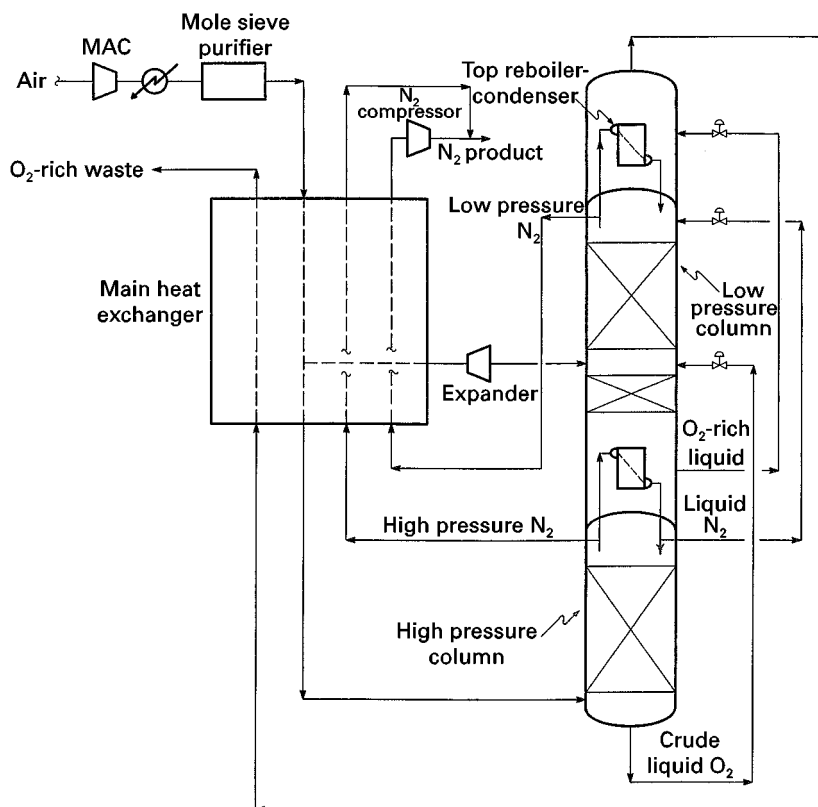

Figure 8 A two-column process for nitrogen production.

crude liquid oxygen from the bottom of the high pressure column is fed to an intermediate location of a low pressure column for further distillation. A low pressure nitrogen vapour stream is recovered from the top of the low pressure column as a second product stream. Another portion of this low pressure nitrogen stream is condensed in the top reboiler-condenser and returned as the major reflux stream to the top of the low pressure column. Optionally, a minor nitrogen reflux stream can also be provided to the low pressure column from the high pressure column. An oxygen-rich liquid stream containing about 70% oxygen is withdrawn from the bottom of the low pressure column, reduced in pressure and vaporized in the top reboiler-condenser. The vaporized stream is then warmed in the main heat exchanger and eventually discarded as a waste stream. Note that the refrigeration for the plant is met by expanding a portion of the gaseous feed air stream to the low pressure column in a turbo-expander. In this process, the feed air is compressed to about 8–9 atm absolute and the pressure of the low pressure column is about 3 atm absolute. A nitrogen compressor is generally used to compress the low pressure nitrogen product stream and then it is combined with the high pressure nitrogen product stream. The typical flow rate of the

combined nitrogen product stream is about 72 mol per 100 mol of the feed air stream. This two-column nitrogen generator and its variations are particularly attractive for enhanced oil recovery where a very large quantity of nitrogen is injected in the wells to maintain pressure.

Ultrahigh Purity Nitrogen and Oxygen Production for the Semiconductor Industry

The fast-growing semiconductor industry uses bulk nitrogen and oxygen gases in the manufacturing of computer chips. The acceptable level of impurities in the supply of these bulk gases has been continually declining over the last decade. Currently, impurities are limited to few parts per billion (p.p.b.) and levels are expected to drop down to parts per trillion levels as wafer sizes increase. The cryogenic distillation process is the only known method of present that, in conjunction with other adsorption and catalytic processes, can meet the stringent demands of ultrahigh purity (UHP) gases.

In addition to the constituent components listed in **Table 1**, air typically consists of several impurities at p.p.m. levels. Hydrogen is a light impurity that is in the range of 1–5 p.p.m.; carbon monoxide is also present at the same levels. There are several

impurities that are heavier than oxygen – methane and higher hydrocarbons and nitrogen oxides are all present in p.p.m. concentrations. When nitrogen is distilled in one of the typical processes discussed earlier, it contains almost all the hydrogen, helium and neon and a major fraction of the carbon monoxide contained in the air. Similarly, a typical high purity oxygen contains all the unacceptable heavier impurities – krypton, xenon, methane and higher hydrocarbons, for example. Clearly the conventional distillation methods need modification to be able to supply the UHP gases.

One early method used to produce UHP nitrogen was to pass the nitrogen from a typical cryogenic distillation process over a bed of a nickel supported on silica to remove the trace levels of oxygen, hydrogen and carbon monoxide. This method is now used for back-up systems since the regular supply of UHP nitrogen is produced directly from the cold box to the semiconductor fabrication plant without any further compression. The pressure of the supply UHP nitrogen is generally 8–10 atm absolute. The feed air after compression is heated to a temperature of about

200°C and passed over a noble metal catalyst such as platinum to oxidize all the carbon monoxide and hydrogen. The exhaust gas is then cooled and passed through the molecular sieve unit. In an alternative process, a separate noble metal catalyst is not used but instead, layers of adsorbent catalysts are supplied within the molecular sieve unit to remove hydrogen and carbon monoxide to p.p.b. level. The impurities-free air is then cooled in the main heat exchanger and distilled in a column similar to the one shown in Figure 7. A large number of separation stages (60–100) are used in this main distillation column to reduce the oxygen concentration in the resulting nitrogen product stream to a level of a few p.p.b.

In addition to stage count, another major difference between the processes of Figures 7 and 9 is the manner in which crude liquid oxygen from the main distillation column is treated. In the UHP nitrogen process of Figure 9, crude liquid oxygen is fed to the top of a short column containing three to six stages of separation. The boil-up at the bottom of this column is provided by condensing a portion of the nitrogen vapour stream from the top of the main (high pressure) distillation column. The nitrogen and oxygen concentration in the vapour leaving the top of the short column is similar to that in air – this stream is called synthetic air. The pressure of the synthetic air is generally greater than 4 atm absolute. To recover

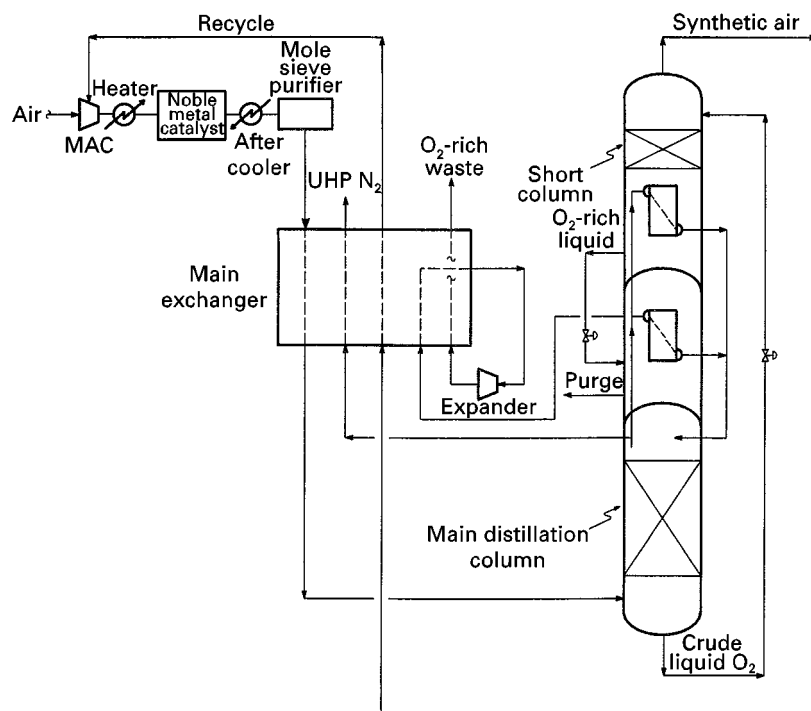

Figure 9 A UHP nitrogen scheme.

the pressure energy, this stream is recycled after further boosting its pressure to that of the main distillation column. In **Figure 9**, synthetic air is fed to an interstage of the main air compressor. This configuration saves the capital cost associated with a separate booster recycle compressor.

Not all the liquid at the bottom of the short column is vaporized; instead, an oxygen-rich liquid containing about 60–70% oxygen is withdrawn. The pressure of this liquid is reduced by 1–2 atm and then it is vaporized in a separate reboiler-condenser to produce another portion of the liquid nitrogen reflux for the main distillation column. A liquid purge stream is taken from this reboiler to prevent the accumulation of hydrocarbons to unsafe levels. The vaporized oxygen-rich stream is then expanded to provide the needed refrigeration for the plant and is eventually discharged as a waste stream.

The reason for modifying the distillation scheme of **Figure 7** to that of **Figure 9** stems from the fact that, in a UHP nitrogen process, the distillation pressure is quite high. In **Figure 7**, high pressure distillation causes the waste stream to vaporize in the reboiler-condenser at a pressure greater than 4 atm. When a large portion of the feed air (in this case 60%) is sent to the turbo-expander at such a high pressure, excess refrigeration is produced. The consequence is that the pressure energy of the waste stream is not utilized effectively and the process becomes inefficient. In contrast, the UHP nitrogen distillation scheme in **Figure 9** recovers nearly half of the crude liquid oxygen stream as a recycle synthetic air stream, thereby reducing the flow to the turbo-expander. In other words, the production of excess refrigeration is avoided and efficient operation is maintained by sending only that portion of the crude liquid oxygen stream needed for the refrigeration to the turbo-expander.

There are several other distillation schemes used for the production of UHP nitrogen. However, all the efficient schemes are based on modification of the scheme in **Figure 7**, such as is shown in **Figure 9**.

Generally, UHP oxygen is required in much smaller quantities (generally 1–5% of the UHP nitrogen production rate). It is essential that not only the concentration of a lighter impurity such as argon be in the p.p.m. to p.p.b. level but also that the concentration of heavier impurities, such as krypton, xenon and hydrocarbons, be no more than a few p.p.b. in the UHP oxygen stream. In contrast to this, a standard-grade oxygen from the process shown in **Figure 4** contains about 0.5% argon and all of the heavier impurities such as methane, krypton and xenon are contained in the feed air.

A UHP oxygen distillation scheme that is a modification to the distillation configuration of **Figure 9** is shown in **Figure 10**.

This modification results from an observation that, as the feed air ascends the main distillation column, all the impurities that are heavier than oxygen are rapidly reduced to nearly zero within a few separation stages. The concentration of oxygen, however, is still at significant levels. Thus, a heavies-free liquid stream is withdrawn from about 10–15 separation stages above the vapour feed air location of the main distillation column. This heavies-free liquid stream contains about 10–20% oxygen and, after pressure reduction to near atmospheric pressure, is fed to the top of the UHP oxygen column. Since the feed to this column only contains components that are more volatile than oxygen, the purpose of the column is essentially to distil off these components from oxygen. Depending on the desired purity of UHP oxygen, 60–100 separation stages are used. Since the amount of UHP oxygen to be produced is low compared to the amount of UHP nitrogen, the boil-up at the bottom of the UHP oxygen column is met by cooling crude liquid oxygen in the sump of this column. The vapour from the top of this column is typically mixed with the discharge stream from the turbo-expander. About 25% of the heavies-free liquid feed to the UHP oxygen column is recovered as UHP liquid oxygen product from the bottom of the column. It is a true credit to the cryogenic distillation industry that the stringent purity demanded by the semiconductor industry can be met without post-treatment.

Liquefaction

Liquid nitrogen and liquid oxygen are produced and stored in a back-up system to supply gases (after vaporization of the stored liquid) in the event of the cryogenic air separation plant shut-down. Liquid may also be supplied in tankers from a central plant location to an end-use site where the consumption of nitrogen and oxygen is not high and economically it is not justifiable to build a dedicated plant. Liquid nitrogen is also used as a source of refrigeration in such applications as food freezing.

In 1895, Carl von Linde built the first industrial-scale air liquefier. His liquefier used a Joule–Thompson (JT) valve to create refrigeration. His genius was the realization that, for the same pressure ratio across a JT valve, the amount of cooling (drop in temperature) increases rapidly as the absolute pressure of air is increased. Therefore, such a liquefier operated at about 125 atm while the pressure across the JT valve dropped to approximately 5 atm. In 1902,

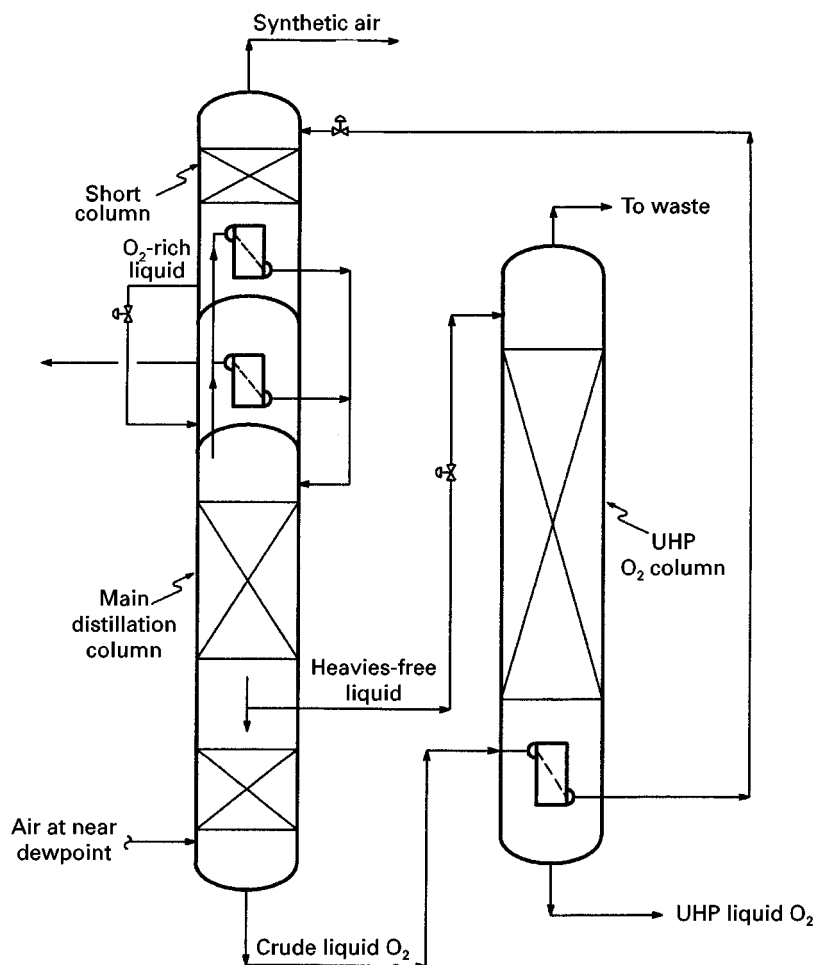

Figure 10 A distillation scheme for UHP oxygen production.

Georges Claude demonstrated that it was possible to lubricate a piston expander with petroleum ether at cryogenic temperatures. He then built an air liquefier using his piston expander. Since this liquefier did not rely on a JT valve to supply all the refrigeration, it was much more efficient than the liquefier built seven years earlier by Linde. In 1935, Kapitza built a piston expansion engine with gas lubrication and in 1939 he built an air liquefier with an expansion turbine. Most modern liquefiers use expansion turbines.

Although the early 'masters' of cryogenics were interested in liquefying air, the focus of modern liquefiers is mainly to liquefy nitrogen. This is due to the dominant use of liquid nitrogen for refrigeration supply. Liquid oxygen is generally produced by supplying some liquid nitrogen as reflux to the low pressure column of a double-column process and by withdrawing an equivalent amount of liquid oxygen from the bottom of this column. The gaseous nitrogen needed for the nitrogen liquefier is provided by any of the suitable air distillation processes described earlier.

Liquefiers that are capable of producing in excess of 1000 tons per day of liquid nitrogen and oxygen are now in operation.

A two-expander nitrogen liquefier is shown in **Figure 11**.

Make-up nitrogen from an air distillation cold box is compressed to about 6 atm in a make-up compressor and is further compressed to a pressure in excess of 27 atm in a recycle compressor. The pressurized nitrogen leaving the recycle compressor is further boosted to a pressure in excess of 45 atm in compressor 1 and compressor 2, and then fed to a heat exchanger for cooling. A portion of the high pressure nitrogen stream is withdrawn near the warm end of the heat exchanger and expanded in a warm expander to provide a portion of the refrigeration needed for the liquefaction. A second portion of the high pressure nitrogen stream is withdrawn from an intermediate location of the heat exchanger and expanded in a cold expander to provide the refrigeration in the cold part of the heat exchanger. The remaining

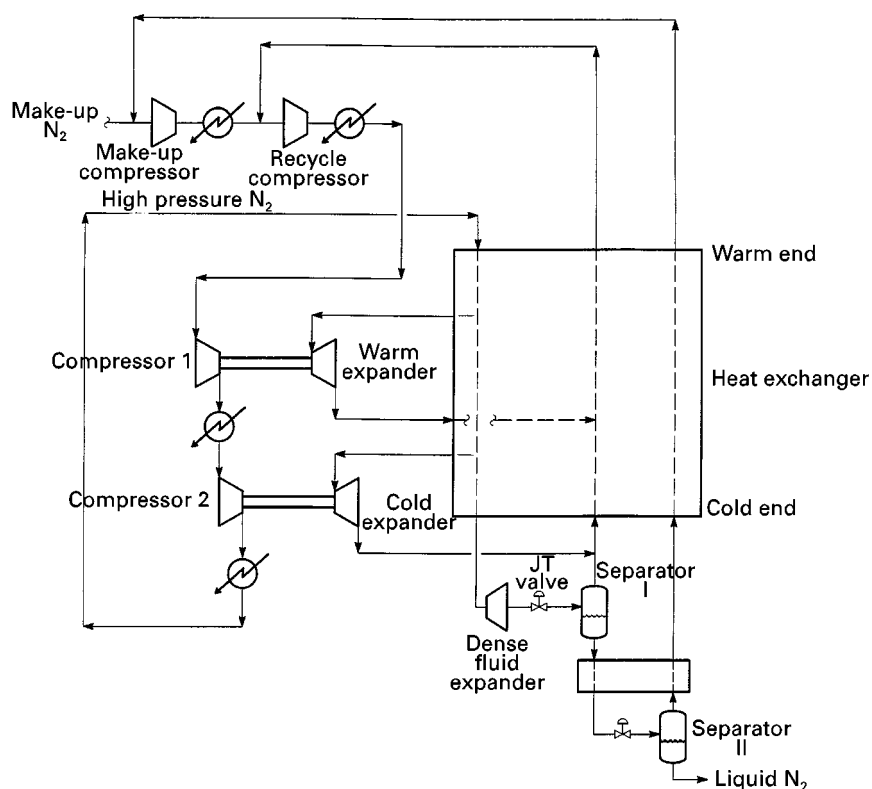

Figure 11 A nitrogen liquefier.

portion of the high pressure nitrogen stream exits the cold end of the heat exchanger at a temperature below -170°C and is sent to an optional dense fluid expander. The pressure drop across this dense fluid expander is maximized, subject to the constraint that very little vapour forms in the exhaust. The pressure of this stream is further reduced to about 6 atm in a JT valve and the resulting two-phase stream is separated in separator I. The vapour from this separator and the exhaust streams from the cold and warm expanders are mixed at appropriate temperatures, warmed and returned to the recycle compressor. The liquid from separator I is further cooled and reduced to near atmospheric pressure through another JT valve. The resulting liquid is collected as liquid nitrogen from separator II and the vapour is recycled to the make-up compressor.

The liquefier shown in **Figure 11** is quite efficient. The use of a dense fluid expander contributes to increased efficiency but its use is optional. The working pressure range of the modern brazed plate and fin aluminium heat exchangers now approaches 100 atm. For increased efficiency, the pressure of the high pressure nitrogen stream is increased to maximum feasible values. Recently, processes using more than two gaseous expanders have been suggested for incrementally higher efficiencies.

In **Figure 11**, if none of the expanders are used then the liquefaction process reduces to the one proposed by Carl von Linde. On the other hand, if the warm expander and the dense fluid expander are removed, then the resulting process is similar to the one used by Georges Claude.

Equipment

Machinery

The selection of a compressor depends on the volumetric flow rate, the operating pressures, the compressor efficiency, its capital cost and the cost of energy. Because of their lower installation cost, centrifugal compressors are chosen over reciprocating compressors when volumetric flow rates and pressure allow their use. Axial compressors are used for large volumetric flow rates. Reciprocating machines are used at very high pressures and small volumetric flows.

For most air plants in the size range of 30–3000 tons per day of oxygen, centrifugal compressors containing three or four stages are used for compressing the feed air. Interstage cooling is provided with cooling water to approximate isothermal compression. A large fraction of the water contained in the feed air

is condensed in these interstage coolers. Most of these compressors are electrically driven; however, steam or gas turbines are occasionally used when economically justified. Air is passed through one or two stages of filtration to remove particulates prior to entry in a MAC. For plants that are larger than 3000 tons per day of oxygen, a combination of axial and centrifugal compressors is used. At the other end of the scale, for small size plants in the size range of less than 30 tons per day of oxygen, inexpensive screw compressors are used. These guidelines for oxygen plants can easily be translated to nitrogen plants, because for the same production rates, a nitrogen plant requires only 30–50% of the feed air flow required by an oxygen plant.

When gaseous oxygen is to be compressed, a centrifugal compressor is used for low to moderate pressures while a reciprocating compressor is used for higher pressures. When oxygen is needed at fairly high pressures, the initial stages of compression may be centrifugal. The design of an oxygen compressor requires careful selection of materials and seals, and total prevention of rubbing contacts to avoid ignition in the presence of high pressure oxygen. Furthermore, an oxygen compressor is generally enclosed in a building with an external barrier to increase the safety of plant personnel. Special test and start-up procedures are also used for oxygen compressors.

Expanders are used to provide refrigeration by extracting work from an expanding fluid. In the expansion process, the temperature of the expanded fluid is reduced. An air separation or a liquefaction plant generally uses a single-stage radial inflow turbine as a standard. For small plants, the work energy from the expander is either dissipated in an oil brake or through an ambient air blower. For medium to large size separation plants and liquefiers, it is essential that the work energy from an expander be recovered to increase process efficiency. This is done by either loading an expander with an electric generator or a compressor for some other process fluid. When an expander is directly coupled to a compressor, the arrangement is called a compander. As seen from Figure 11, companders are widely used in liquefiers. Expanders used in the cryogenic air separation and liquefaction industry typically have isentropic efficiencies in the range of 85–90%. The dense fluid expanders are essentially reverse-running liquid pumps (Figure 11).

Front-end Purification

The compressed air from a main air compressor must be cleaned of impurities such as water, carbon dioxide and some hydrocarbons to avoid plugging at

cryogenic temperatures. The original plants used recuperative heat exchangers which were later replaced by regenerators in 1930 upon their invention by Matthias Fränkl. Around the mid-1950s, owing to the introduction of large brazed aluminium plate and fin heat exchangers, the regenerators were replaced by reversing heat exchangers. Recuperators, regenerators and reversing heat exchangers all operated to freeze the impurities within the device – complete removal of these trace components was never achieved. Beginning in the early 1980s, reversing exchangers were replaced with ambient temperature adsorption beds. Today almost all cryogenic air separation plants use molecular sieve vessels to remove impurities.

A typical two-bed adsorption system for air purification is shown in Figure 12. Each vessel is filled with 13X (Na-X zeolite) molecular sieve. This sieve has an excellent capacity for carbon dioxide and water removal. Sometimes an additional layer of alumina is used at the entrance for bulk water removal to decrease the energy demand during regeneration. While one bed is on stream, the other bed is being regenerated. In Figure 12, bed A is on stream and bed B is being regenerated. A bed is on stream for a pre-specified period until carbon dioxide is about to break through the bed. At this point the feed air is directed to another bed. The pressure of the spent bed is reduced to near atmospheric pressure and a hot dry gas in the temperature range of 150–200°C is passed through the bed to desorb the adsorbed impurities. After the impurities have been removed, the bed is cooled by a flow of cool dry gas and it is then ready to be brought on

Figure 12 A front-end system for air purification.

stream. The dry gas used for regeneration is generally a portion of the gas exiting the cold box. Regeneration gas flow rate is typically in the range of 10–20% of the feed air flow. For oxygen plants, the regeneration gas is a portion of the nitrogen stream.

Heat Exchangers

Around the mid-1950s, large brazed aluminium plate and fin heat exchangers were commercially introduced. They readily became the heat exchangers of choice for cryogenic air separation and liquefaction plants. In this type of heat exchanger, corrugated fins are sandwiched between plates to form a passage for gas flow. The use of fins provides increased surface area for heat transfer. Typical fin heights range between 5 and 9 mm; fin spacing can be as low as 1 fin per mm. A heat exchanger block is formed by stacking passages. Generally, flow through individual passages is countercurrent with a warming stream in one passage and a cooling stream in the adjacent passage. A heat exchanger block can easily handle multiple warming and cooling streams. Plate and fin heat exchangers are applied in virtually all the heat exchanger services of an air separation plant. They are used as main heat exchangers, reboiler-condensers and subcoolers. The maximum size and pressure rating of these heat exchangers depend on the manufacture; however, heat exchangers 1200 mm wide by 1200 mm stack height by 6000 mm long with a pressure rating up to 50 atm can easily be found. For large size plants, multiple heat exchangers are used in parallel and careful attention is paid to the flow distribution in the manifolds.

Distillation

Until the 1980s almost all air distillation was performed in columns containing sieve trays. Due to the close relative volatility between argon and oxygen and the purity of the products, columns with over 100 separation stages are not uncommon. Therefore, tray spacing is generally 150 mm or less. Pressure drop across a large number of trays in the low pressure column increases the pressure of the boiling fluid in the low pressure column sump. This increases the pressure of the condensing nitrogen at the top of the high pressure column. In turn, the pressure of the air at the discharge of the main air compressor is increased. This leads to an increase in power consumption. As a result, there is an incentive to use a liquid–vapour contact device with lower pressure drop.

Today, most modern cryogenic air separation plants use low pressure drop structured packing in one or more of the distillation columns. The pressure drop through structured packing is only one-fifth to one-tenth that of a trayed column. The use of struc-

tured packing has led to more than 3% power savings for a typical oxygen plant. It has also allowed the use of over 175 stages of separation in the side argon column of Figure 6 for the production of argon with less than 5 p.p.m. oxygen through distillation. This eliminates the need for a second deoxidation (Deoxo) process using hydrogen and a catalyst, thereby making pure argon production much simpler.

Cold Boxes

The cryogenic equipment is enclosed in an insulated enclosure termed a cold box. A rectangular cold box consists of a steel frame with panels of sheet metal. It also provides structural support for the equipment. Cylindrical cans with insulation are also used in certain applications. Mineral wool was used for insulation prior to the late 1940s. Starting around 1948, a powdered insulation called perlite was increasingly used. The advantage of perlite is that installation costs are lower and cold boxes can be insulated with greater uniformity, leading to reduced heat leak and improved plant efficiency.

Materials of Construction

Early plants used copper or copper alloys to fabricate vessels and piping. Austenitic stainless steels were occasionally used. In the later 1950s, with the development of welding techniques for aluminium, its use became the most popular. This occurred because aluminium and aluminum alloys are easily available and are low cost and light weight. Cryogenic liquid containers are also constructed from low carbon 9% nickel steel.

Safety

Many materials react with pure oxygen, so great care is taken in the selection and clean-up of materials that come into contact with oxygen. Potential ignition sources must be minimized. All impurities that come into contact with oxygen, especially unsaturated hydrocarbons, must be reduced to safe levels. To avoid hydrocarbon build-up, generally a small purge stream is taken from the sumps where oxygen-rich liquids are being boiled. The combustion hazard increases as pure gaseous oxygen is compressed to higher pressures and therefore, special care should be taken in the compression and handling of high pressure oxygen gas.

AIRBORNE SAMPLES: SOLID PHASE EXTRACTION

Introduction

Organic material in the atmosphere may exist in either the gas phase or in particles. For the purposes of this chapter, atmospheric organic material will be divided into three classes, defined by the phase distribution of the organic material in the atmosphere. Gas phase compounds will include those organic compounds which are present only in the gas phase. This will include essentially all non-aromatic organic material with fewer than about 12–14 carbon atoms. Nonvolatile organic material will include those compounds which are present in particles and whose concentrations in the gas phase are negligible compared to the particulate material. Semi-volatile organic material includes those compounds which are present in equilibrium between the gas and particulate phases in the atmosphere and for whom the concentrations in both phases are significant. The collection of gas phase and nonvolatile organic material is relatively straightforward. However, the

accurate determination of the phase distribution of semi-volatile organic material requires the use of diffusion denuder technology.

Correct assessment of the contribution of fine particulate carbonaceous material to various atmospheric processes is dependent on the accurate determination and characterization of fine particulate organic material as a function of particle size. Several studies have shown that about one-third of the mass of fine particulate matter (dia. $<2.5\ \mu\text{m}$) collected on filters in remote desert regions of the Southwest U.S. is organic compounds and elemental carbon. Similar fractions of carbonaceous material are found in particles collected on filters in western urban areas. In the eastern United States sulfate is the major component of filter collected airborne fine particles. However, organic material comprises one-fourth or more of the fine particulate mass. In the Northwest, organic material has been found to be the dominant fine particulate component. However, unless proper sampling procedures are used to collect particulate material, the composition of organic material in fine particles will be significantly underestimated due to losses from the semi-volatile particulate organic fraction during sample collection, i.e. a 'negative' sampling artifact.

Several studies have also indicated the presence of a 'positive' artifact in the determination of particulate organic compounds collected on a quartz filter, due to the adsorption of gas phase organic compounds by the quartz filter during sampling. Data obtained using sampling systems with two quartz filters in series suggest that quartz filters collect at least some gas phase organic compounds. In addition, particulate material collected on a filter can also absorb some gas phase organic compounds. The adsorption of organic compounds by a second quartz filter has been shown to be reduced, but not eliminated, in samples collected in the Los Angeles Basin if a multi-channel diffusion denuder with quartz filter material as the denuder collection surface precedes the quartz filters. This artifact can be eliminated by the use of activated charcoal at the denuder surface. Recent experiments have shown that the quartz filter artifact can result both from the collection of gas phase organic compounds and from the collection of semi-volatile organic compounds lost from particles during sampling. Thus, results available to date suggest that both a 'positive' and a 'negative' artifact can be present in the determination of particulate phase organic compounds using two tandem quartz filters.

Collection of Gas Phase Organic Material

A well validated technique for the collection of gas phase organic material for subsequent analysis is the use of SUMMA stainless steel canisters. If the canisters are properly cleaned before use and analysed within a few weeks of sample collection, valid results can be obtained for most gas phase compounds.

A second method which has frequently been used to collect gas phase organic materials consists of the use of a filter to remove particulate material, followed by a sorbent bed to collect the gas phase organic compounds. This approach is not valid if (1) the gas phase organic material is oxygenated or polar and therefore capable of being absorbed by a quartz filter or by organic material collected by the particle removing filter, or (2) the gas phase organic material is semi-volatile and therefore, may be present on and lost from particles during sampling (see following section). The absorption of organic material by various types of filters has been reviewed. Teflon has been suggested to be relatively inert to absorption artifacts, but this filter is not amenable to the determination of total carbon. Glass fibre and cellulose membrane filters both absorb significant quantities of gas phase organic material. Quartz membrane filters are suitable for the determination of total carbon, but they also can absorb significant quantities of gas phase

organic material. This is illustrated in **Figure 1** which shows the analysis of total carbon for a filter which was preceded and not preceded by a charcoal based diffusion denuder to remove gas phase material. The large peak seen in the absence of a diffusion denuder is gas phase organic material collected by the quartz filter. A similar peak (plus some higher temperature material) is seen on a second quartz filter which is not preceded by a denuder.

Materials which have been validated as sorbents for the removal of gas phase organic compounds include polyurethane foam (PUF), poly(oxy-m-terphenyl-2',5'-ylene), Tenax, copolymers of styrene and divinylbenzene (XAD), Chromosorb and charcoal. Of these sorbents, Tenax is best suited for the collection of very low molecular weight organic material and Chromosorb or XAD are effective for collection over a wide range of molecular weights. A caution is that many of the sorbents can produce spurious results due to reactions during sample collection and each of the sorbents can be difficult to clean for the detection of trace substances. Thus, for example, a PUF cartridge produces mutagenic compounds upon extraction with methanol and Tenax forms decomposition products during sampling.

Collection of Non-Volatile Organic Material

Compounds which are sufficiently volatile that they exist essentially only in the gas phase can be collected on any filter suitable for total particle collection, such as quartz or Teflon filters. Quartz filter are usually used when the determination of total carbonaceous material in addition to the identification of specific compounds is desired. However, if only specific compound identification is desired, the use of Teflon filters avoids the complication associated with the absorption of gas phase material by the filter. However, if the target species include compounds which are reactive or unstable, they may be altered by chemical reactions associated with the sampling process. Examples of potential problems are given in the following sections.

Collection of Semi-Volatile Organic Material

To address the issues of both 'positive' and 'negative' artifacts in the sampling of particulate phase organic compounds, several groups have constructed and tested sampling systems employing diffusion denuders, filters and sorbent filters. The data obtained to date with these sampling systems show that particulate

Figure 1 Temperature-programmed volatilization analysis of quartz filters (A) not preceded and (B) preceded by a denuder with charcoal impregnated filter surfaces. The large initial peak seen in (A) but not in (B) is due to the absorption of gas phase organic material by the quartz filter not preceded by a diffusion denuder to remove gas phase organic compounds.

phase organic compounds have been significantly underestimated by the collection of particles with only a filter. The collection of gas phase compounds by a quartz filter may produce a significant 'positive' artifact (Figure 1), but a much larger negative error usually results from the loss of 20–80% of the particulate phase semi-volatile organic material during sampling. This sampling artifact must be considered in the collection of semi-volatile particulate organic compounds. Accurate collection procedures for semi-volatile organic compounds must meet the following two criteria:

1. Organic compounds initially present in the gas phase which can be adsorbed onto particles or the filter must be distinguished from semi-volatile organic compounds lost from particles during sampling.
2. Organic compounds initially present in the particulate phase and lost from particles during sampling must be captured during sampling separate

from compounds which are present in the gas phase in the atmosphere.

These two criteria cannot be met by any sampling procedure in which the particulate phase organic compounds are collected before the collection or separation of gas phase organic compounds because the gas phase organic compounds and organic compounds volatilized from particles become indistinguishable. Thus, it is necessary first to remove the gas phase organic compounds and then to collect the particulate phase organic compounds with a sampler which will collect all organic material, gas and particle. This can be accomplished using diffusion denuder sampling technology.

The BOSS and BIG BOSS Diffusion Denuder Samplers

Diffusion denuder sampling systems for the determination of total fine particulate organic material have been developed at Brigham Young University.

The objectives which guided the development of these sampling systems were:

1. The sampling system should have a flow rate sufficient to enable measurement of low concentrations of particulate carbonaceous material and to allow the detailed chemical characterization of particulate organic material, e.g. flow rates of from 30 to 300 L min⁻¹ were considered desirable.
2. The sampler should have a diffusion denuder capable of removing all gas phase semi-volatile organic compounds which are in equilibria with compounds in the particulate phase in the atmosphere.
3. The diffusion denuder of the sampler should be effective in removing all gas phase compounds which can be adsorbed by a quartz filter or by collected particles during sampling.
4. The capacity of the diffusion denuder for the removal of gas phase organic compounds should be high enough that samples can be collected at the target flow rates over sampling periods of several days to weeks.
5. Particle losses during the passage of sampled air through the diffusion denuder should be small.
6. The sampler after the diffusion denuder should collect both particles and any semi-volatile organic material lost from particles during sampling with high efficiency.
7. The collection materials used in the sampler should be compatible both with the determination of total carbonaceous material and with the detailed chemical characterization of particulate organic material.

The BOSS (BYU Organic Sampling System) requires two different samplers as shown schematically in Figure 2:

1. A charcoal impregnated filter (CIF), multi-channel, parallel plate diffusion denuder followed by a filter pack containing quartz and CIF filters. The denuder removes gas phase organic compounds. The quartz filter after the denuder collects fine (<2.5 μ m) particles. The organic compounds collected by the CIF sorbent filter in this sampler are semi-volatile organic compounds lost from the particles during sampling and a small fraction (about 5%) of the gas phase organic material not collected by the diffusion denuder.
2. A quartz filter followed by a CIF diffusion denuder and a CIF sorption filter. The quartz filter collects particles and any gas phase organic compounds which can be absorbed by quartz, both those ori-

Figure 2 Schematic of the BOSS. Non-volatile particulate carbonaceous material is determined from analysis of $T_{1,1}$. Semi-volatile carbonaceous material lost from particles is determined from analysis of $CIF_{1,1}$, corrected for the denuder inefficiency determined from analysis of $CIF_{2,1}$.

ginally in the gas phase and those lost from the particles during sampling. The denuder then removes gas phase compounds passing the quartz filter. Any gas phase compounds not removed by the denuder are then collected by the CIF sorbent filter. This system is used to determine independently the gas phase organic compounds not collected by the denuder to correct the data obtained with the CIF filter of Sampler 1.

The various 47 mm diameter filters of the BOSS are contained in Teflon filter packs (University Research Glass, Model 2000-30F) with the filter packs holding

the quartz filter in Sampler 2, Figure 2, being modified so that the outlet is identical to the inlet to allow for convenient connection to the diffusion denuder (University Research Glass, Model 2000-30FB). The diffusion denuder is based on a design originally reported by Fitz (1990). Each denuder is comprised of 17 (4.5×58 cm) strips of Schleicher and Schuell charcoal impregnated filter paper which are separated at the long edges by 2-mm rods. The multi-parallel plate array of filter strips is contained within a (5×5 cm) square aluminium tube. The entire assembly is nominally 90 cm in length to accommodate 58 cm sorbent filter strips and two nominally 15 cm long flow straightening sections ahead of and behind the denuding section. The multi-channel diffusion denuder is designed to have acceptable efficiency for the removal of gas phase organic material in the denuder, negligible loss of particles to the denuder during sampling, and high capacity for the collection of gas phase organic material. The total capacity of the CIF multi-channel denuder has not been directly measured. However, no degradation of the efficiency of the denuder for the collection of gas phase organic compounds was seen during continuous operation at 40 L min^{-1} for over two months or for sampling at 180 L min^{-1} for continuous periods equivalent to seven and fourteen days in the Los Angeles Basin, for ten days in the Mohave Desert, or for twelve days at Research Triangle Park, NC.

The CIF (Schleicher and Schuell, Inc.) strips in the diffusion denuder are used as received from the manufacturer. The 47 mm CIF (Schleicher and Schuell, Inc., No. 508) filters are cleaned with dichloromethane and dried at 200°C before use. Alternately, a 47 mm Carbon EMPORE (3M) filter may be used. The Carbon EMPORE filters may be used as received from the manufacturer, however, flow through these filters is limited to about 7 L min^{-1} . The 47 mm quartz filters (Pallflex, 2500 QAT-UP) are pretreated by firing at 800°C for four hours prior to sample collection. The flow through the two samplers of the BOSS, Figure 2, is controlled at about 40 L min^{-1} . A version of the BOSS using a shortened denuder (27 cm CIF strips) with a flow of from 4 to 20 L min^{-1} has also been described. The CIF or Carbon EMPORE filters may also be replaced with an XAD sorbent bed. The XAD (Rohn & Haas) is cleaned by first sonicating 10 times with CH_3OH to remove very fine particles and then Soxhlet extracting for 24 hours sequentially with CH_3OH , CH_2Cl_2 and $\text{C}_2\text{H}_5\text{OC}_2\text{H}_5$.

The efficiency of removal of gas phase organic compounds by the CIF denuder (or by an annular denuder configuration) is described by eqn [1]:

$$C/C_o = 0.819e^{-22.5(D_j L W/4Fd)} \quad [1]$$

where C_o and C are the concentrations of organic compounds entering and exiting a section of the denuder, respectively, D_j is the diffusion coefficient of the gas phase organic compound(s) at the experimental conditions, L and W are the length and effective width of the denuder section, F is the flow and d is the space between the denuder surfaces. A plot of the log of the amount collected in equal length sections of a denuder versus the distance from the start of the denuder through the section should be linear with a slope of $-22.5 D_j W/4Fd$. The expected deposition gradient was observed for organic material collected by a CIF based denuder containing two parallel sheets of the charcoal impregnated filter material. The slope of the line describing the deposition pattern for the collection of ambient gas phase organic compounds gives an average diffusion coefficient for the collected gases of $0.052 \pm 0.008 \text{ cm}^2 \text{ s}^{-1}$. This diffusion coefficient gives a calculated effective average molecular weight of 160 ± 25 . This average molecular weight is consistent with the majority of the organic material which has been shown to be collected by the diffusion denuder. The deposition pattern was also consistent with the measured efficiency of the CIF denuder for the removal of gas phase organic compounds.

The importance of the particulate organic compounds which have not been identified in past studies where particles are collected on a filter will be dependent on the chemical composition and the size distribution of the particulate organic compounds, both those lost from the particles during sampling and those remaining on the particles after sampling. A high-volume, multi-component diffusion denuder sampling system (BIG BOSS) for the determination of the size distribution and chemical composition of fine particulate organic compounds using diffusion denuder sampling technology has been developed and tested.

The BIG BOSS uses a variety of size selective virtual impactor inlets to control the particle size of the particles introduced to the diffusion denuder sampler. The inlet system is a modification of a high-volume, multi-jet virtual impactor. The nominal total flow through all systems of the BIG BOSS is $0.9 \text{ m}^3 \text{ min}^{-1}$ inlet flow. This flow is divided among four systems, each with a coarse particle minor flow stream and a fine particle major flow stream. Two of the four systems have an inlet cut of $2.5 \mu\text{m}$. The other two systems are designed to operate with an inlet cut of 0.8 and $0.4 \mu\text{m}$ (see Tang, 1994).

The PC-BOSS Denuder Sampler

The combination of the technology used in the previously described BIG BOSS sampling system and the

Figure 3 Schematic of the PC-BOSS. The composition of fine particulate matter is determined from analysis of the two filter packs after the denuder. The efficiency and losses of the fine particle concentrator is determined by comparison of sulfate on Q_2 with that on Q_1 or T_1 .

Harvard particle concentrator results in the Particle Concentrator-Brigham Young University Organic Sample System (PC-BOSS) shown schematically in **Figure 3**. The system has been optimized to meet the following criteria: (1) removal of at least 75% of the gas phase material before the sampled aerosol is passed through the diffusion denuder, (2) efficiency, >99% for the removal of SO_2 , HNO_3 and gas phase semi-volatile organic material, (3) determination of particle mass, carbonaceous material and nitrate with

a diffusion denuder sampler, (4) operation on less than 20 amps of 110 V power.

The inlet to the sampler is a Bendix cyclone with a particle cut of $2.3 \mu\text{m}$ aerodynamic diameter at an inlet flow of 150 L min^{-1} . Following the inlet, 20 L min^{-1} is diverted to a filter pack to provide data for calculating the efficiency of and losses in the PC-BOSS particle concentrator. The remaining flow enters the virtual impactor particle concentrator. The design and evaluation of the particle concentrator has

been previously described. The particle concentrator separates most of the gas phase material into the major flow and leaves particles larger than the cut point (about $0.1\ \mu\text{m}$) along with a significantly reduced fraction of the gas phase material in the minor flow. The performance of the particle concentrator for collection of ambient samples with the PC-BOSS was evaluated as a function of the minor to major flow ratio, and the distance between the accelerator and receiver slits of the virtual impactor. The optimum design uses a single particle concentrator with a 9.5 cm long slit and a distance between the accelerator and receiver slits 1.5 times the slit width of 0.32 mm. The minor flow (25% of the total $150\ \text{L min}^{-1}$ flow) containing concentrated particles enters the BOSS diffusion denuder. The denuder is followed by two parallel filter packs (Figure 3). The filter pack containing a 47 mm quartz filter (Pallflex, pre-fired) followed by a 47 mm charcoal impregnated filter is used to determine fine particulate carbonaceous material, including semi-volatile organic material lost from the particles during sampling. The second filter pack contains 47 mm Teflon (Gelman Zefluor) and nylon (Gelman Nylasorb) filters to determine mass, sulfate and nitrate, including any nitrate lost from particles during sampling.

The IOVPS and IOGAPS Denuder Samplers

Researchers at Lawrence Berkeley Laboratories have developed an annular denuder sampling system, the Integrated Organic Vapour/Particle Sampler (IOVPS) with an XAD-IV based diffusion denuder for the measurement of SVOC. This diffusion denuder sampler is similar in design and operation to the BOSS systems described above. The IOVPS is shown schematically in Figure 4. An advantage of the IOVPS sampler is that the gas phase material collected by the denuder can be easily recovered for organic compound chemical characterization and quantitation. Current disadvantages of the sampler are the total carbonaceous material is not determinable in the denuder or post-filter XAD sorbent beds (Figure 4) and the capacity of the denuder limits the length of time over which the denuder may be used from hours to days.

The denuder of the IOVPS system is prepared by adhering very fine mesh XAD to a glass multi-annular denuder surface. The adhesion of the finely ground XAD to the sandblasted glass is strong enough that the coating is resistant to removal by handling, solvent washing and air sampling. Quantitation of gas phase organic compounds removed by the IOVPS denuder is accomplished by extraction with a suitable solvent and analysis by GC or GC/MS. The collection efficiency of these denuders for various gas phase

organic compounds has been shown to be close to that predicted by eqn [1]. A 5-channel denuder with 1 mm spacing in the annulus and a coating length of 38 cm has been used for most applications of the IOVPS denuder.

The capacity of the IOVPS XAD based denuder is dependent on two factors: (1) the capacity of the XAD surface for a given compound and (2) the time required to elute a dilute concentration of a given gas down the XAD column length. The dominant factor appears to be the movement of collected gas phase material down the XAD column. As a result, studies using the IOVPS denuder have generally been limited to chamber studies where the sampling period is short or to ambient studies where the sample collection occurred only over a few hours. By increasing the length and surface area of the denuder (including using parallel denuders) prototype systems have been developed by Lawrence Livermore Laboratory and the Atmospheric Environment Service of Environment Canada (IOGAPS, Integrated Organic Gas and Particle Sampler) which are capable of sample collection for up to 48 hours. Comparisons of results obtained from 24 hour IOGAPS and sequential 4 hour IOVPS data where the annulus width of the IOGAPS was 1.5–3.0 mm with a residence time of 2.6 s indicated there was about 10% breakthrough of naphthalene in the IOGAPS. A redesign with an annulus width of 1.0–1.4 mm is expected to eliminate this problem.

Particle losses to the wall of the IOVPS denuder has been evaluated in several studies. The results are essentially identical to those reported above for the BOSS and BIGBOSS samplers. With face velocities of around $20\ \text{cm s}^{-1}$ through the denuder, losses are less than 2%. At higher face velocities of 35 to $50\ \text{cm s}^{-1}$, the losses increase to about 5–7%. These losses are comparable to that seen for conventional annular denuders.

Other Diffusion Denuder and Related Samplers

Diffusion denuder sampling techniques have also been developed and used by several other investigators to determine fine particulate organic material. The focus of these studies has been on the determination of specific organic compounds. Krieger and Hites have used short sections of capillary gas chromatographic columns as a diffusion denuder and determined concentrations of gas and particulate phase polychlorinated biphenyl (PCB) and polyaromatic hydrocarbon (PAH) compounds. Coutant *et al.* have described the development of a circular multi-channel diffusion denuder for the study of PAH in ambient air. However, results on field studies using the sampling system have not yet been published. The

Figure 4 Schematic of the IOVAPS (from Gundel, 1999). The denuders contain XAD as the gas phase organic sorbent. Non-volatile particulate carbonaceous material is determined from analysis of the filters in either of the filter packs. Semi-volatile carbonaceous material lost from particles is determined from analysis of the denuder d3.

Atmospheric Environment Service of Environment Canada has been involved since 1984 in the development and use of a diffusion denuder sampler for the determination of PCBs and chlorinated hydrocarbons. The instrument uses a silicone gum/Tenax-coated, multi-tube, annular, diffusion denuder to remove the target organic compounds. Turpin *et al.* have developed a sampling system which corrects for the loss of semi-volatile organic compounds during sampling by removal of most of the gas phase material from the particles in a diffusion separator sampling system. The system has been evaluated for the

collection of PAH. All of the systems which have been described by other research groups collect samples at a flow rate of a few L min^{-1} . One advantage of the use of the diffusion denuder sampling systems described above is that the attainable high flow rate, 200 L min^{-1} , allows for more collected material and a wider range of analyses on the collected samples.

Residence Time in the Denuder

The efficiency of a diffusion denuder sampler for the removal of gas phase material can be improved by

increasing the residence time of the sampled aerosol in the denuder. However, the residence time can only be increased within limits. Since the diffusion denuder reduces the concentration of gas phase semi-volatile organic material, semi-volatile organic material present in the particles passing through the denuder will be in a thermodynamically unstable environment and will tend to outgas SVOC during passage through the denuder. The residence time of the aerosol in the denuder should be short enough to prevent significant loss of particulate phase SVOC to the denuder. Various studies have suggested that the residence time in the denuder should be less than about 2 s. The residence times in the various denuder designs described above are about 1.5, 0.2, 0.2 and 1.4 s for the BOSS (or PC-BOSS), BIG BOSS, IOVPS and IOGAPS denuders, respectively.

Changes in Chemical Composition during Sampling

The preceding sections have outlined sampling systems designed to identify correctly the atmospheric gas and particulate phase distribution of collected organic material. An additional sampling artifact which has been little considered in the collection of atmospheric sampling is the potential alteration of organic compounds as a result of the sampling process. These alterations appear to result from the movement of ambient air containing oxidants and other reactive compounds past the collected particles. The addition of NO_2 (<1 p.p.m.) or O_3 (<200 p.p.b.) to the sampled air stream (0 to 5°C) for a high volume sampler reduced the concentrations of benzo(a)pyrene and benzo(a)anthracene from a few up to 38%, with the observed reduction increasing with increased concentration of the added gases. Spiking a filter with an amine resulted in an increase in measured concentrations of nitrosoamines in both the filter and a following XAD sorbent bed for a mid-volume sampler. Similar results have been obtained for the exposure of a deuterated amine on a filter to NO_x . When Tenax columns spiked with deuterated styrene and cyclohexane were exposed to p.p.m. concentrations of ozone or halogens, oxygenated and halogenated compounds were shown to be formed. Similar oxidation of aldehydes and PAN during sampling has been observed. Collected PAH compounds can be oxygenated and/or nitrated on a filter but 1-nitropyrene has been shown to be resistant to additional nitration. These various chemical transformations of collected organic compounds can be eliminated by removal of the gas phase oxidants, NO_x , HNO_3 , etc., prior to collection of the particles. The PC-BOSS denuder described above should be

effective in eliminating most of chemical transformation artifacts since reactive gases are removed by the charcoal denuder which precedes the particle collection filter.

Application of Diffusion Denuder Samplers to the Determination of Semi-Volatile Organic Material

The application of diffusion denuder samplers to the determination of gas and particulate phase semi-volatile organic material is illustrated with results from three different studies, one each using the BIG BOSS, PC-BOSS and IOVPS samplers.

Semi-volatile organic compounds lost from particles during sampling and subsequently collected by an XAD-II trap and semi-volatile organic compounds retained by the quartz filters during sampling have been chemically characterized for <2.5 μm particles in BIG BOSS samples collected at Azusa in the Los Angeles Basin. The XAD-II sorbent beds included significant concentrations of aliphatic, acidic and aromatic organic compounds. Similar compounds were also detected in the GC-MS analysis of the filter extracts. However, the compounds retained by the filter were of higher molecular weight. The distribution of compounds lost from particles during sampling and remaining on the particles during sampling is illustrated by the GC/MS results for paraffinic compounds (Figure 5).

The pattern seen in Figure 5 is typical of results obtained for all classes of compounds and all samples studied to date. For those compounds which have been characterized, the envelopes of each class of compounds remaining in the particles and lost from the particles overlap. For each compound class, the more volatile compounds predominate in the material lost from the particles and collected in the XAD-II bed during sampling. In contrast, the higher molecular weight organic compounds are retained by the particles during sampling. For example, particulate n-tetradecane and n-pentadecane are found only in the XAD-II bed and not in the particles after sampling (Figure 5). Hydrocarbons lower in molecular weight than these two compounds are found in comparable concentrations in the XAD-II beds of both Samplers 1 and 2 of the BOSS (Figure 2) indicating they originate mainly from the breakthrough of some fraction of the gas phase component of these species. In contrast, n-tetracosane and higher molecular weight aliphatic hydrocarbons are retained by the particles during sampling and are not found in the XAD-II sorbent beds (Figure 5). Compounds of intermediate molecular weight, e.g. n-decosane, are partially lost and partially retained by the particles. Also illustrated

Figure 5 GC/MS data ($m/z = 85$) for paraffinic compounds; (A) retained by particles and (B) lost from particles during collection on a filter (from Tang, 1994).

by the GC-MS data is the increased tendency for lower molecular weight semi-volatile organic compounds to be retained by the particles during sample collection as the polarity of a given molecular weight compound increases. For example, *n*-heptadecane (MW 226) is largely lost from particles during sampling (Figure 5). However, lauric acid (MW 214) and fluoranthene (MW 202) are largely retained by the particles during sampling.

Results for the determination of PAH compounds in indoor air obtained with the IOVPS and with a conventional filter-sorbent sampler are given in Figure 6. As indicated in Figure 6(A), about 90% of the phenanthrene, pyrene and chrysene are present in the gas phase. However, about 60% of the more volatile phenanthrene (MW 178) and pyrene (MW 202) are lost from the filter of the filter pack during sample collection. In contrast, the loss of the less volatile chrysene (MW 228) was negligible. These

results are comparable to those given above for the Azusa study with the BIG BOSS.

Recent studies have indicated that the U.S. Environmental Protection Agency (EPA) PM_{10} air quality standard does not provide adequate human health protection because the fine particle ($PM_{2.5}$) component of PM_{10} is related to observed health effects at concentrations substantially below the PM_{10} standard. As a result, EPA has promulgated a $PM_{2.5}$ air quality standard. In order to implement the new $PM_{2.5}$ standard, a Federal Reference Method (FRM) for fine particulate monitoring has been proposed (see Schaefer, 1997). The $PM_{2.5}$ FRM is a single filter pack sampling method with gravimetric determination of the collected mass.

For the reasons outlined above, the FRM will tend to not measure semi-volatile fine particulate constituents. The amount of semi-volatile material is expected to be a substantial fraction of the total $PM_{2.5}$

Figure 6 Retention and loss of particulate PAH compounds during sampling. (A) The lower concentrations determined by a filter pad, compared to IOVPS, is due to losses from particles during sampling. (B) Concentrations of both particle and gas phase PAH with the IOVPS.

Figure 7 Average composition of PM_{2.5} in Riverside CA, including semi-volatile ammonium nitrate and organic material lost during sampling from particles collected on a filter.

mass observed in many urban areas. As a result, the proposed Federal Reference Method may under-determine fine particulate mass. A comprehensive field study to evaluate the PC-BOSS and compare with results obtained by other PM_{2.5} sampling methods, including the FRM has been conducted in Riverside, California. Riverside was chosen for the study because high particulate pollution resulting from summer inversions is expected. Both annual and 24 hour maximum concentration of PM₁₀ exceeded the federal standards in 1995 and high concentrations of particulate semi-volatile ammonium nitrate and organic materials are expected to be present in this area.

The average result for the determination of the composition of fine particulate matter in Riverside during August and September 1997 are given in **Figure 7**. Substantial amounts of both ammonium nitrate and semi-volatile organic material were lost from the filters of both the PC-BOSS and the PM_{2.5} FRM. The average loss of ammonium nitrate (34%, 1.7 $\mu\text{g m}^{-3}$) was smaller than that for the semi-volatile organic material (54% of total fine particulate organic material, 9.5 $\mu\text{g m}^{-3}$). As a result of the loss of these species, the PM_{2.5} FRM lost an average of 39% of the fine particulate material during the collection of the sample.

The results obtained in these three examples illustrate the importance of correctly sampling for semi-volatile particulate organic material.

ALCOHOL AND BIOLOGICAL MARKERS OF ALCOHOL ABUSE: GAS CHROMATOGRAPHY

F. Musshoff, Institute of Legal Medicine, Bonn, Germany

Copyright © 2000 Academic Press

The use of alcoholic beverages is probably the most ancient social habit worldwide, but alcohol abuse has generated severe problems. Chronic and/or acute alcohol intoxication has been demonstrated to be connected with serious pathologies, suicides, homicides, fatal road and industrial accidents and many criminal offences. Alcoholism is a widespread social, medical and economic problem in a large section of the population of nearly all ethnic groups. Therefore, it is of great importance to have diagnostic tools (biological markers) to detect excessive alcohol consumption and alcoholism. This article deals with gas chromatographic techniques to determine excessive alcohol consumption. The following parameters are described: ethyl alcohol and congeners, ketone bodies, ethyl glucuronide, fatty acid ethyl esters and condensation products like salsolinol.

Ethyl Alcohol

The most obvious and specific test for heavy drinking is the measurement of blood, breath or urine alcohol (ethyl alcohol). However, this simple test cannot distinguish between acute and chronic alcohol consumption, unless it can be related to an increased tolerance of alcohol. According to the American National Council on Alcoholism (NCA), the first-level criteria for the diagnosis of alcoholism are blood alcohol exceeding 1.5 g L^{-1} without gross evidence of intoxication, over 3 g L^{-1} at any time, or over 1 g L^{-1} in routine examination. The determination of alcohol has already been the subject of many reviews. The most important facts are summarized here.

As a first step, various pitfalls and analytical problems such as interference in alcohol analysis induced by cleaning the skin with ethanol or isopropanol before expert venepuncture should be borne in mind. The stability of ethanol during storage is a problem. The main factors affecting alcohol determination in stored blood are the duration and temperature of storage, with negligible losses in the frozen state, and the presence of a preservative. Three mechanisms accounting for these changes are: oxidation (highly

temperature-dependent, needing oxygen from oxyhaemoglobin), the growth of microorganisms metabolizing ethanol (inhibited by sodium fluoride at $\geq 0.5\%$, w/v) and diffusion from containers owing to closure failure. A further potentially interfering factor, especially in autopsy cases, is ethanol production in (postmortem) tissues by bacteria and yeasts. Freezing seems to be the best precaution in order to maintain the original alcohol levels.

Gas chromatography (GC) is *par excellence* the all-purpose technique for the determination of volatile molecules, such as alcohols and related compounds. Almost all GC methods for ethanol determination allow the simultaneous measurement of a wide range of other volatile analytes (alcohols, aldehydes, ketones, glycols, etc.). Although some of the earlier techniques have become obsolete, the incorporation of advances such as headspace chromatography have extended the popularity of chromatography. The analytical conditions of the

most interesting methods are summarized in Tables 1 and 2. The following classification has been used.

Direct Injection

Methods using direct injection of whole blood suffer from the adsorption of undesirable compounds (proteins and other macromolecules) on the column and, consequently, in most procedures prior dilution or centrifugation have been used.

With Extraction

For a prior extraction step organic solvents such as *n*-propyl acetate, *n*-butanol or dioxan are used.

With Distillation

Sample and internal standard in sodium tungstate/sulfuric acid are subjected to distillation. The distillate is injected into the column and detection is performed by thermal conductivity or flame ionization.

Headspace Methods

The most important advantage is the prevention of column contamination.

Methods requiring solvent extraction or distillation should be considered obsolete mainly because they are time- and sample-consuming and not susceptible to automation. Direct injection and headspace GC are the only techniques in general use that can be fully and easily automated. The description of direct injection technique is mostly connected with the dilution of the sample (mostly with aqueous solutions containing the internal standard) and with the injection of small volumes. Additional protection from contamination can be obtained with a glass sleeve inserted in the injection port or with a pre-column glass insert filled with a silanized glass wool plug. Triton X-100 has been reported to improve the performance of the direct injection of serum by acting as a protein-dispersing agent. Protein precipitation, which can be carried out in conjunction with the addition of the sample with the internal standard, has been proposed as a simple means of overcoming the problems related to the injection of whole blood. Headspace GC for blood alcohol analysis was the subject of a review in 1975 by Machata who made many contributions to

the development of this technique. Chromatograms are shown in **Figure 1**. Headspace analysis prevents any contamination of the column and injector with involatile material and is preferred in routine laboratories. Also, reproducibility is often better than in direct injection (typical within and between-run coefficients of variation < 1.5% and < 2.5%, respectively). Analytical problems arise concerning the choice of the sample equilibration temperature; oxidation of ethanol takes place at temperatures exceeding 40°C, but higher temperatures increase the air–blood partition coefficient and, consequently, the sensitivity. The conversion of ethanol into acetaldehyde is reportedly inhibited by the addition of sodium nitrite or sodium dithionite. Increased sensitivity due to a salting-out effect is obtained using sodium chloride, sodium nitrite, potassium carbonate, sodium fluoride and ammonium sulfate. In such non-ideal solutions, the vapour pressures of volatile components at a fixed temperature have been reported to depend on the water content of the sample.

An additional advantage of headspace technique is the complete elimination of matrix-related effects, which prompted its use for the analysis of tissues, stool samples or other biological material. A new procedure is the headspace–solid-phase microextraction

Figure 1 Representative headspace gas chromatograms determining alcohol concentrations in human serum samples. A, Blank (serum); B, 0.48 g L^{-1} ; C, 1.95 g L^{-1} . Retention times: EtOH, 1.65 min; t-butanol, 2.2 min.

(HS-SPME) technique, based on the adsorption of analytes directly from the headspace on to a coated fused silica fibre. Various fibres for different analytes are available and a $65 \mu\text{m}$ Carbowax/divinylbenzene coating is used for alcohols.

Alcohols can be efficiently separated with different GC columns and the choice is often only based on practical considerations such as total analysis time, cost, column life and the possibility of using the same column for different analyses. Carbowax 20M is superior to Carbowax C coated with Carbowax 1500 for the determination of acetaldehyde and methanol and is also superior to adsorption chromatography on Porapak Q and Chromosorb 102. Separation is generally carried out under constant temperature conditions; temperature programming has been used for the simultaneous determination of less volatile compounds. Detection is universally carried out by a flame ionization detector (FID). Capillary chromatography (Carbowax 20M) allows a higher separation performance and easier coupling with mass spectrometry, which is preferred for the determination of lower volatile alcohols.

Congeners

Besides ethanol, alcoholic beverages contain up to 800 flavour compounds and some of these congeners can be found in sufficient quantities to allow their detection in the blood of the consumer. There are

characteristic differences in the congener content of alcoholic beverages. A close correlation between the consumed amount of a congener alcohol and the resulting blood level can be helpful for the evaluation of allegations concerning alcohol intake in forensic cases, especially when determining types of drinks and when estimating the time of drinking (Figure 2). The sensitivity of conventional headspace GC is sufficient for blood ethanol determinations down to 0.01 g L^{-1} , but for the detection of congener alcohols the limits of detection had to be improved to 0.01 mg L^{-1} . Some procedures contain special sample preparation steps, which include homogenization by ultrasound and/or ultrafiltration. As the long chain alcohols are partly or completely bound to glucuronic acid, incubation with β -glucuronidase is necessary. Using a temperature programme and capillary columns the loading capacity can be enhanced by a cryofocusing technique.

Methanol is an important congener of most alcoholic beverages. Metabolism of methanol via liver alcohol dehydrogenase is inhibited by ethanol levels exceeding 0.4 g L^{-1} . Consequently, excessive and prolonged drinking results in high blood methanol levels. Increased blood methanol levels are frequently found in drunken drivers and alcoholics. On the basis of these findings, blood methanol levels exceeding 10 mg L^{-1} have been suggested to be an indicator of alcoholism. Additionally higher concentrations of acetone and propanol-2 have been proposed as an indication of drinking behaviour. This phenomenon is caused by reciprocal formation through the alcohol dehydrogenase system. If the sum of the concentrations exceeds 9 mg L^{-1} , heavy drinking is suspected. However, due to the effects of metabolic disorders (ketosis, diabetes, hunger, physical stress), the significance has been regarded as very low.

Ketone Bodies

In many forensic cases alcohol abusers have been found dead and the cause of death cannot be ascertained. In order to examine the possible role of ketoacidosis as the cause of death the concentrations of ketone bodies (acetone, acetoacetate, D- β -hydroxybutyrate) have to be determined in postmortem blood specimens. The phenomenon of ketoacidosis is often seen as typical in periods of abstinence with low intake of food. It is due to the accumulation of D- β -hydroxybutyrate and acetoacetic acid. The accumulation is probably the result of various factors such as volume depletion and starvation, which have a lipolytic effect.

A routine procedure is a coupled enzymatic headspace GC method (Figure 3). This procedure is based

Figure 2 Total ion chromatograms ((A) selected ion monitoring and (B) full scan mode) of a standard solution of 28 substances relevant in congener analysis in concentrations of 2 mg L^{-1} (methanol 10 mg L^{-1} , acetaldehyde 0.5 mg L^{-1}). 1, Acetaldehyde; 2, methanol; 3, ethanol; 4, propionaldehyde; 5, acetone; 6, propanol-2; 7, methyl acetate; 8, *t*-butanol (internal standard); 9, *i*-butyraldehyde; 10, propanol-1; 11, *n*-butyraldehyde; 12, methyl ethyl ketone; 13, ethyl acetate; 14, butanol-2; 15, *i*-butanol; 16, *i*-valeraldehyde; 17, 2-methylbutyraldehyde; 18, butanol-1; 19, *n*-valeraldehyde; 20, 1,1-diethoxyethane; 21, 3-hydroxybutanone-2; 22, 3-methylbutanol-1; 23, 2-methylbutanol-1; 24, *i*-butyl acetate; 25, pentanol-1; 26, butyl acetate; 27, ethyl lactate; 28, hexanol-1. GC parameter: HP 5890 II GC with HP MSD 5972, equipped with a DB 624 column ($60 \text{ m} \times 0.32 \text{ mm}$, $\text{df} = 1.8 \text{ }\mu\text{m}$); helium flow 1 mL min^{-1} ; injector 150°C ; detector 200°C ; oven initially 30°C for 8 min, 3°C min^{-1} up to 180°C . (Reproduced with permission from Roemhild W (1998) Congener analysis by means of 'headspace'-GC/MS. *Blutalkohol* **35**: 10.)

on enzymatic dehydrogenation of *D*- β -hydroxybutyrate into acetoacetate and subsequent decarboxylation of this compound into acetone. Three portions are taken from each sample. One portion is heated to 60°C in a headspace sampler, which gives the free acetone. Acetoacetate is converted into

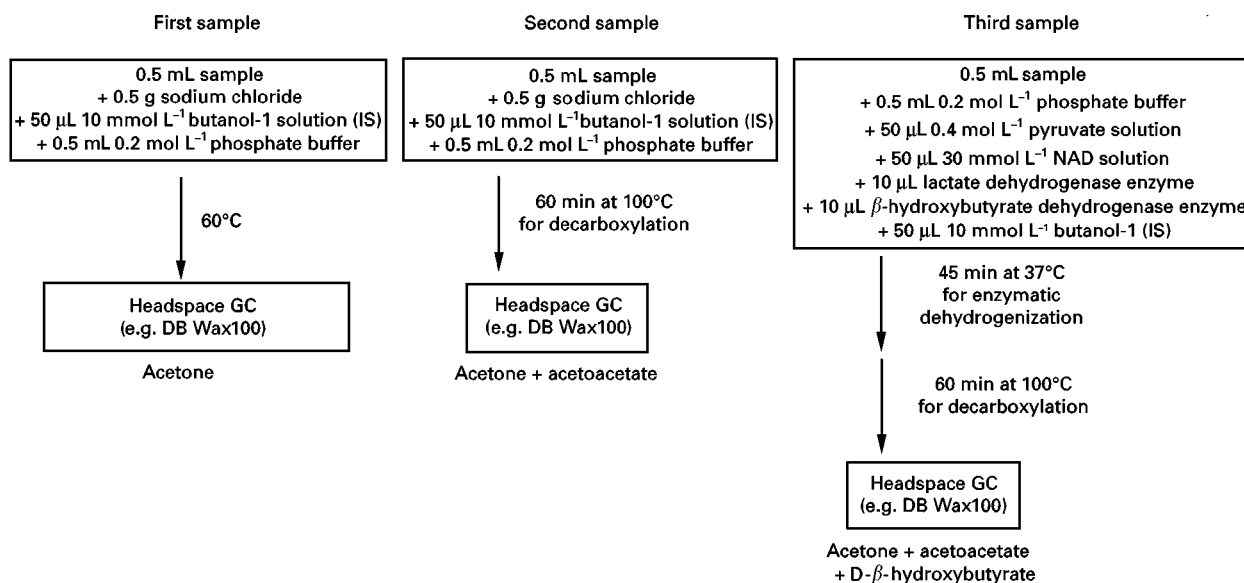

Figure 3 Schematic presentation of a standard procedure for determination of ketone bodies in blood specimens. Three portions are taken from each sample to determine free acetone and the sums of acetone + acetoacetate and acetone + acetoacetate + *D*- β -hydroxybutyrate.

acetone by decarboxylation at 100°C in the second portion. This part gives the combined amount of acetone and acetoacetate. In the third portion, D- β -hydroxybutyrate is first enzymatically dehydrogenized into acetoacetate by D- β -hydroxybutyrate dehydrogenase and then decarboxylated into acetone. Quantification of acetone then yields the molar equivalent of the total ketone bodies. Omission of the enzymatic stage of the analysis allows quantification of the molar equivalent of acetone and acetoacetate present, and the subtraction of this value from total ketone quantitation allows calculation of the D- β -hydroxybutyrate concentration.

The reported ketone body concentrations vary a lot. It was held that if the ketone body concentration of the blood exceeds 531 $\mu\text{mol L}^{-1}$ and if there is no other plausible cause of death in a group of alcohol abusers, the term ketoalcoholic death should be used. In another study it was pointed out that very high levels, above 10 mmol L^{-1} , are indicative of profound alcoholic ketoacidosis.

Ethyl Glucuronide

Ethyl glucuronide (EtG) is a minor metabolite of ethanol and is formed from ethanol by conjugation with uridine diphosphate (UDP)-glucuronic acid. EtG has been detected in human urine, serum and clipped hair samples of ethanol consumers. The formation of EtG depends on the serum ethanol concentration. It was shown that serum EtG concentrations higher than 5 mg L^{-1} may indicate alcohol misuse, especially if the serum ethanol concentration is less than 1 g L^{-1} . The EtG concentration declines exponentially with a half-life of 2–3 h and testing for EtG is restricted to a period of about 6–18 h after drinking, depending on the ethanol dose and individual metabolism. In forensic cases testing is predominantly indicated when the ethanol determination gives nega-

tive results and consumption is denied. For retrospective studies detection of EtG in hair samples also seems to be possible. However, if excessive ethanol consumption over a period of months or years provokes a stimulation of glucuronyltransferase in the liver, the extent of the EtG formation might be an indicator of ethanol abuse.

For the determination of EtG in serum the sample is precipitated with acetone or methanol and the dried supernatant is derivatized by addition of acetic anhydride and pyridine. A mass spectrum of the triacetyl derivative is shown in Figure 4. Hair samples are extracted with methanol, including treatment by ultrasound prior to derivatization. On an OV-1 capillary column, the retention index is 1920. Gas chromatography–mass spectrometry (GC-MS) was performed with an electron energy of 70 eV and gave the following m/z values (intensities higher than 20% in parentheses): 85 (53), 88 (41), 101 (38), 113 (66), 114 (42), 115 (100), 117 (47), 130 (25), 157 (73), 142 (25) and 143 (28); there is no parent peak. An m/z value of 303 (1%, M-45) indicates that EtG is decarboxylated.

Fatty Acid Ethyl Esters

Fatty acid ethyl esters (FAEE) are formed by an enzyme-mediate esterification of ethanol with fatty acids or fatty acyl-coenzyme A. It has been shown that FAEE and the FAEE synthase are predominantly present in those organs most often damaged by ethanol abuse, notably the pancreas and liver. This has led to speculation that FAEE, lipids more hydrophobic than triglycerides, are mediators of ethanol-induced organ damage. Following ethanol consumption by humans, FAEE have also been found in serum lipoproteins. Recently it was reported that the concentration of FAEE in the blood closely parallels the concentration of blood ethanol. In serum samples of

Figure 4 Mass spectrum of the triacetyl derivative of ethyl glucuronide.

subjects who had blood ethanol concentrations $> 1.5 \text{ g L}^{-1}$, FAEE concentrations ranged up to 2500 nmol L^{-1} and were still detectable 24 h after ethanol ingestion. However, serum FAEE may evolve into both a short-term and long-term marker of ethanol ingestion. In forensic cases the determination of a recent intake of ethanol may be necessary. A negative blood ethanol with a positive FAEE test is consistent with ethanol intake 4–24 h before blood collection. Additionally it has been reported that FAEE are present in significantly higher amounts in postmortem adipose tissues obtained from individuals with a history of chronic alcohol abuse, with ethanol-induced organ damage at autopsy and zero blood ethanol at the time of death (mean \pm SEM equals $300 \pm 46 \text{ nmol g}^{-1}$) compared to those from a control group without a history of chronic ethanol ingestion, without ethanol-related organ damage and with zero blood ethanol at the time of death ($43 \pm 13 \text{ nmol g}^{-1}$; Figure 5).

Studies on FAEE frequently involve isolating the compounds by liquid–liquid extraction and thin-layer chromatography (TLC) prior to identification and quantification. The isolation of FAEE by these methods is especially suitable for adipose tissue. Sample material (1–2 g) is extracted in acetone (10% w/v) and the lipids are separated by TLC on silica gel using a petroleum ether/diethyl ether/acetic acid (75:5:1) solvent system. Fatty acid ethyl esters, $R_F = 0.5$, are identified by comparison with standards and eluted from the silica gel with acetone. The reproducibility of this procedure is sometimes a problem and the method often results in low yields. The small amounts of the very hydrophobic FAEE present in human plasma after ethanol ingestion are commonly lost during extraction. As with fatty acids, FAEE moieties which contain two or more double bonds can be oxidized within minutes on a dried TLC plate and are thereby lost prior to quantification. To enhance the recovery of the relatively small amounts of FAEE, an effective solid-phase extraction (SPE) method for isolation is preferred. Extraction of FAEE from serum is initiated by the addition of acetone/hexane solution. After being dried and re-suspended in hexane the extract is applied to an aminopropyl silica SPE column with simultaneous elution of FAEE and cholesteryl esters from the column with hexane. The FAEE can then be separated from cholesteryl esters, if necessary, by chromatography on an octadecylsilyl (ODS) SPE column and elution with isopropanol/water (5:1, v/v). Recently a relationship between various levels of alcohol consumption and the appearance of fatty acid methyl esters (FAME) in postmortem tissue samples have been reported. In addition, this connection is suppos-

Figure 5 Analysis of FAEE from human plasma. Lipids from sera of patients with markedly elevated blood ethanol levels were extracted into hexane and applied to an aminopropyl silica column. Lipids eluted from the column were dried under nitrogen to a small volume and an aliquot injected into a gas chromatograph – mass spectrometer (WCOT Supelcowax capillary column). The peaks identified as FAEEs are labelled: E 16:0, ethyl palmitate; E 17:0, ethyl heptadecanoate; E 18:0, ethyl stearate; E 18:1, ethyl oleate; E 18:2, ethyl linoleate; E 20:4, ethyl arachidonate. (Reproduced from Bernhardt TG *et al.* (1995) Purification of fatty acid ethyl esters by solid-phase extraction and high-performance liquid chromatography. *Journal of Chromatography B* 675: 189, with permission from Elsevier Science.)

edly caused by the accumulation of the congener alcohol, methanol, during chronic alcohol abuse.

The GC analysis of FAME after esterification of lipids was the subject of an excellent review by Eder in 1995 and the comments are applicable to FAEE. The most critical step in the GC analysis of FAME is sample introduction. The classical split injection technique, which is the most widely used procedure, has the potential disadvantage of boiling-point discrimination. Cold injection of the sample, either on-column or by programmed-temperature vaporization, does not present this problem and is therefore preferred. Separation of FAME can be carried out with nonpolar, polar and very polar stationary phases. The polarity influences the retention times, especially those of polyunsaturated FAME. The resolution capability is highest in columns with very polar phases. However, very polar phases have a shorter lifetime

Table 3 Selection of procedures for determination of tetrahydroisoquinolines (TIQ) and tetrahydro- β -carbolines (THBC)

<i>Sample material</i>	<i>Analytes</i>	<i>Work-up procedure</i>	<i>Packing (mesh)/column (m \times mm I.D.)</i>	<i>Limit of detection</i>
Tissue and body fluids	Various TIQs and catecholamines	Al ₂ O ₃ extraction; fluoracylation; GC with electrochemical detection (GC-ECD)	3–5% OV-17, SE-30, SE-54, XE-60 or GE XF-1150 on Gas Chrom Q (80–100) (6 ft \times 2)	0.2–50 pg per sample
Brain	Salsolinol	Liquid–liquid reextraction; fluoracylation; GC-ECD	3% OV-1 on Gas Chrom Q (100–120) (6 or 8 ft \times 2)	10 pg per sample
Urine	TIQs	Liquid–liquid reextraction; trimethylsilyl (TMS) derivatives; GC with mass spectrometry (MS)	3% OV-1 on Gas Chrom Q (100–120) (6 ft \times 2)	
Blood, platelets, plasma and brain	Various THBCs	Liquid–liquid reextraction; heptafluorobutyl (HFB) derivatives; GC-MS	2% SP-2250 (4 ft \times 2) or SE-30 (15 \times 0.3) on Chromosorb W-HP (100–120)	1 pmol per sample
Brain and biological fluids	Salsolinol and others	Al ₂ O ₃ extraction with deuterated standards; fluoracylation; GC-MS	1% OV-17 (2.5 \times 2) or SE-54 (25 \times 0.2)	1 pmol per sample
Biological fluids and foods	THBCs	Liquid–liquid extraction with deuterated standards; fluoracylation; GC-MS	SE 52 W COT (20 \times 0.25)	0.3 pmol mL ⁻¹
Brain	Nor salsolinol	Amberlite extraction; propionyl derivatives; GC-MS	2% SP-2250 on Chromosorb W-HP (100–120) (4 ft \times 2)	1 ng g ⁻¹
Brain and foods	TIQ and <i>N</i> -methyl-TIQ	Liquid–liquid extraction; HFB derivatives; GC-MS	3% OV-17 on Shimalite (80–100) (2 \times 2.5) or OV-1 or OV-101 or DB-17 (25 \times 0.2 mm)	0.25 ng per sample
Brain and foods	Various THBCs	Liquid–liquid extraction; pentafluorobenzyl (PFP) derivatives; GC-MS	SE 52 WCOT (20 \times 0.35 mm)	0.1–0.5 ng per sample
Brain and foods	1-methyl-THBC	Liquid–liquid extraction; TFA derivative; GC-MS with negative CI	OV-1701 (25 \times 0.25)	10 fg per sample
Urine	Various THBCs and TIQs	Combined liquid–liquid and solid-phase extraction; carbomethoxy/propionyl derivatives; GC-MS	OV-1 (12 \times 0.2 mm)	100 pg mL ⁻¹
Urine	1-methyl-THBC	Liquid–liquid extraction; derivatization with (<i>R</i>)-(-)-2-phenylbutyryl chloride (PBC)-enantiomeric composition; GC-NICI-MS	RTX-cross-bonded SE-30 (30 \times 0.25 mm)	
Plasma and urine	Salsolinol and others	Solid-phase extraction over phenylboronic acid (PBA) cartridges; two-step derivatization (TMS-PBC)-enantiomeric composition; GC-MS	BGB-silaren (30 \times 0.32 mm)	100 pg mL ⁻¹
Urine	Salsolinol	Extraction and derivatization in one step by Schotten–Baumann two-phase reaction utilizing pentafluorobenzoyl-chloride	DB-5 (30 \times 0.25)	10 fmol mL ⁻¹
Brain	THBC and 1-methyl-THBC	Liquid–liquid extraction; TFA derivatives; GC-NCI-MS	RTX-cross-bonded SE-30 (30 \times 0.25 mm)	20 pg per sample
Urine	Salsolinol and norsalsinol	Solid-phase extraction (PBA); propionyl derivative; GC-MS	OV-1 (12 \times 0.2 mm)	100 pg per sample

TFA, trifluoroacetyl; CI, chemical ionization; NCI, negative chemical ionization; TMS, trimethylsilyl.

Figure 7 Identification of dopamine, (R)-(+)- and (S)-(–)-salsolinol and norsalsolinol in an authentic urine sample of a chronic alcoholic.

extensively documented. Salsolinol, which might be formed *in vivo* by ring cyclization of dopamine with acetaldehyde, is one of the most discussed tetrahydroisoquinolines. Several studies have been done to improve analytical techniques for identification in human urine, plasma, brain and cerebrospinal fluid samples. Poor assay specificity and possible artefact formation of the alkaloids during work-up and storage have been suggested to be responsible for controversial reports on the detection of these compounds in mammalian tissues and fluids after alcohol intake. The variability of reported levels of Salsolinol might also be a result of variables, including dietary conditions during the experiments or the duration of ethanol ingestion and analytical problems associated with the detectability of the analytes. The presence of TIQ and THBC compounds has been established using (radioenzymatic) TLC methods, high performance liquid chromatography coupled with electrochemical or fluorescence detection, or GC procedures mostly combined with mass spectrometry (Table 3). Recently, it has been considered that the (R)-(+)- and (S)-(–)- enantiomers of salsolinol do not exert identical biological activities. Thus, methods for the determination of the enantiomeric composition of endogenous salsolinol have been developed (Figures 6 and 7). More experimental work is necessary to determine whether alcohol really has an influence on the biosynthesis of salsolinol or other condensation products and if the (S)-(–)-salsolinol enantiomer is a sufficient clinical marker to distinguish between alcoholics and nonalcoholics.

Conclusion

Several chemical abnormalities associated with excessive alcohol consumption are useful in the diag-

nosis of alcoholism. Additionally, in forensic cases information can be helpful to evaluate allegations concerning alcohol intake, especially when determining the types of drinks and estimating the time of drinking. In these problems GC procedures measuring the concentration of ethyl alcohol and congeners or EtG can be helpful. The determination of ketone bodies is a diagnostic tool in a prospective postmortem toxicology analysis in alcoholics for considering a ketoalcoholic death. Further studies are necessary to determine the connection between alcohol abuse and the formation of FAEE and condensation products. Further investigations could lead to important pathophysiological bases of alcohol drinking behaviour and ethanol-induced organ damage and ultimately to better forms of prevention and therapy.

Introduction

Simple aldehydes, such as formaldehyde, acetaldehyde and acrolein, are known to be hazardous air pollutants. Aldehydes are emitted from incomplete burning of various organic compounds and from various chemicals, and are formed by photochemical reaction with hydrocarbons in the atmosphere.

Volatile ketones are used as solvents in various chemical plants and laboratories and are emitted into the atmosphere. The toxicity of ketones is, in general, not as high as that of aldehydes. Carbonyl compounds are significant in environmental chemistry, i.e. in rainwater and as a photochemical oxidant.

Separation of aldehydes and ketones is very important for the determination of volatile aldehydes. Usually, analysis of aldehydes is performed by derivatization and gas chromatography (GC) or high performance liquid chromatography (HPLC). Selective and sensitive gas chromatographic methods for separation of aldehydes and ketones are described below.

2,4-Dinitrophenylhydrazone Derivatization

2,4-Dinitrophenylhydrazone (DNPH) derivatives of aldehydes and ketones have been used in gas chromatography for many years. The reaction procedure of aldehyde or ketone is as follows:

Kallio *et al.* analysed 15 carbonyl compounds (aldehydes and ketones) known to be flavour components by derivatization/GC with DNPH. The DNPHs of the carbonyl compounds were prepared by shaking 100 µL of each compound with 100 mL of a saturated solution of DNPH in aqueous 2 mol L⁻¹ hydrochloric acid and allowing the mixture to stand at room temperature overnight. The precipitated DNPHs were dissolved in ethyl acetate, then analysed by GC-FID or dissolved in benzene and analysed by GC-ECD (electron-capture detector). Packed columns with silicone stationary phases were used. Relative retention times of DNPHs of aldehydes and ketones on one of these columns are listed in Table 1

Table 1 Relative retention times (*R*) of 2,4-dinitrophenylhydrazones of carbonyl compounds

Carbonyl compound	2% SE-30 column 200–270°C ^a <i>R</i>

and a typical chromatogram of DNPHs of carbonyl compounds is shown in Figure 1. The peaks of the DNPHs of propanal, propenal and acetone are not separated under these conditions. The sensitivity was of the order of nanograms of carbonyl compounds when FID was used and five-hundred times greater with an ECD.

Saito *et al.* reported an improved GC method with DNPH for the determination of trace low molecular weight aliphatic carbonyl compounds in auto exhaust. They used a glass capillary column, 30 m × 0.27 mm i.d., coated with OV-17 and operated isothermally at 210°C. Aldehydes and ketones in the exhaust were selectively collected by passing 600 ml min⁻¹ of exhaust gas through two impingers which were connected in series and which contained hydrochloric acid saturated with DNPH. The derivatives were extracted twice with chloroform in a separating funnel. After concentration by evaporation under a stream of nitrogen, anthracene was added as internal standard, and 1 µL of the solution was injected into a GC equipped with an FID. Six aliphatic aldehydes and three aliphatic ketones were analysed (Figure 2). The derivatives of C₃ carbonyl compounds, propionaldehyde, acetone and acrolein, were completely separated, and simultaneously determined with formaldehyde and acetaldehyde. The minimum

detectable concentrations of formaldehyde, acetaldehyde and acrolein were 85, 140 and 190 ppb, respectively, for a 10 L gas sample with a relative standard deviation of less than 8%. Using this method, formaldehyde, acetaldehyde, propionaldehyde, isobutyraldehyde, acetone, acrolein, methyl ethyl ketone and methyl isopropyl ketone (or butyraldehyde) were measured in gasoline engine exhaust gas.

Benzylloxime Derivatization

Derivatization of simple aldehydes and ketones to benzylloximes was developed by Magin. The reaction proceeds as follows:

The GC used for the analysis of these derivatives was equipped with a nitrogen-selective detector and

Figure 1 Chromatogram of a mixture of 2,4-dinitrophenylhydrazones of carbonyl compounds on a 2% SE-30 column. 1, Formaldehyde; 2, acetaldehyde; 3, acetone; 4, 2-butanone; 5, 2-butenal; 6, hexanal; 7, heptanal; 8, octanal; 9, nonanal. Programmed temperature analysis from 200 to 270°C (4°C min⁻¹) on a Perkin-Elmer F-11 chromatograph equipped with a hydrogen flame ionization detector. Injected sample: 1.0 µL of ethyl acetate containing about 1000 ng of each of the derivatives. Attenuation 128, range 1. (Reproduced with permission from Kallio H *et al.* (1972). Gas-liquid chromatographic analysis of 2,4-dinitrophenylhydrazones of carbonyl compounds. *Journal of Chromatography* 65: 355.)

a glass capillary column (12 m \times 0.4 mm i.d.) coated with a 0.4 μ m film of free fatty acid phase (FFAP); helium was used as the carrier gas. The column temperature programme was 100–180°C at 2°C min⁻¹; the temperature was kept at 180°C to the end of the analysis. The retention times of the benzyloximes of a number of aldehydes and ketones (1–7 carbon atoms) are shown in Table 2. The results show almost complete separation under these conditions.

Magin also reported the application of the benzyloxime-GC analysis of aldehydes and ketones to the semi-quantitative analysis of simple monocarbonyls in cigarette smoke. The smoke was passed through a silica gel column to trap the carbonyls, followed by elution with water. About 15 mL of eluted solution was collected in a screw-capped bottle, and the benzyloximes of the carbonyls were prepared. Separation was accomplished by a temperature-programmed 12 m glass capillary FFAP column. An internal standard (hexanal) was added both as a reference for retention time determination, and as an aid in estimating the amounts of the individual carbonyls in the smoke samples. Levels of some carbonyls in the cigarette whole smoke samples are shown in Table 3. One problem with this method was that acetaldehyde, one of the major carbonyl compounds in cigarette smoke, could not be determined since peaks corresponding to the benzyloxime derivative of acet-

aldehyde appeared in the reagent blanks. Mass spectra of these peaks were identical to the spectra of the genuine acetaldehyde derivatives, but the source

in the blanks was unknown. Another problem was the lack of reproducibility from run to run. For this reason, the method was described as semi-quantitative.

Pentafluorophenylhydrazone Derivatization

A sensitive and selective GC analysis of lower aliphatic carbonyl compounds as their pentafluorophenylhydrazones was described by Hoshika and Muto.

The general procedure for the preparation of the pentafluorophenylhydrazone derivatives was as follows: 0.5×10^{-3} mol of lower aliphatic carbonyl compound was added, using a 100 μL microsyringe, to 1 mL methanol containing 1.01×10^{-3} mol pentafluorophenylhydrazine (PFPH). The mixture was allowed to stand overnight at room temperature. A 1 μL volume of the solution was injected into the GC. The acetone, acrolein and propionaldehyde derivatives were separated on a 30 m \times 0.25 mm i.d. glass capillary column coated with polyethylene glycol 20 M at 130°C with an FID. This temperature compares favourably with the 200°C column temperature necessary with DNPH derivatives.

A procedure for the GC determination of low molecular weight carbonyl compounds in aqueous

solution as their pentafluorophenylhydrazones and its application to such compounds produced by photolysis of α -amino acids were reported by Kobayashi *et al.* (Figure 3). The calibration graphs for formaldehyde, acetaldehyde and isobutyraldehyde showed good linearity in the range 10–40 μg . Solutions of DL-alanine, DL-valine, DL-leucine or DL-isoleucine in phosphate buffer containing mercury (II) chloride were irradiated in a quartz vessel with a 20 W blacklight lamp (300–400 nm) as a light source for 300 h and the mixtures were measured by this method. Two peaks corresponding to formaldehyde and acetaldehyde were observed for valine.

Pentafluorobenzoyloxime Derivatization

Pentafluorobenzoyloxime (PFBOA) was synthesized by Nambara *et al.* as a new derivatizing agent for GC of ketones using electron-capture detection. Kobayashi *et al.* reported a GC analysis of low molecular weight carbonyl compounds in aqueous solution as their *O*-pentafluorobenzoyloximes. The reaction procedure of aldehyde or ketone is as follows:

The retention times of 13 *O*-pentafluorobenzoyloxime (*O*-PFBO) derivatives of carbonyl compounds relative to the internal standard obtained on XE-60 and other columns are shown in Table 4. When some carbonyl compounds react with PFBOA, two peaks are obtained, corresponding to *syn*- and *anti*-isomers formed by the condensation reaction with PFBOA:

Good linearity of response was obtained for formaldehyde, acetaldehyde, isobutyraldehyde and diethyl ketone in the range 1–50 μg in 0.5 mL of aqueous solution. The utility of PFBOA was compared with that of PFPH. The formation of the *O*-PFBO derivatives of aldehydes was easily achieved with a much lower concentration of PFBOA than that required for PFPH. The derivatization of aldehydes with PFBOA is complete in 20 min at room temperature, but the reaction with ketones proceeds slowly (within 24 h). The PFBO derivatives are much more volatile than the corresponding pentafluorophenylhydrazones and therefore the separation can be carried out at lower temperatures (70–100°C). It was shown that the PFBO derivatives are stable in ethyl acetate at room temperature for several days.

Table 4 Relative retention times of the *O*-pentafluorobenzoyloximes of carbonyl compounds

Aldehydes in air are important as pollutants and photochemical products because they are irritants to the skin, eyes and nasopharyngeal membranes. Trace amounts of formaldehyde in air was determined as the PFBO derivative using GC-ECD by Nishikawa *et al.* Sub-ppb levels of formaldehyde in air could be determined in this way. Although the FID or ECD can be used with PFBO derivatives, the FID has poor sensitivity and in some cases the peaks of the derivatives suffer interference from co-existing materials with both detectors. In the case of analysis of samples with a complex matrix such as exhaust gas or emission gas, the thermionic detector (TID) is more effective. The TID is very sensitive and selective to nitrogen compounds such as oximes and can therefore be used with advantage for the analysis of aldehydes as PFBOA derivatives in automobile exhaust and emission gas. Gas (2–30 L) was collected by bubbling the exhaust through two impingers connected in series. Each impinger contained 10 mL of the absorption solution (300 mg L⁻¹ PFBOA·HCl in ethanol). The sample gas was drawn at a rate of 0.5 L min⁻¹. After sampling, the absorbed solution was made up to 20 mL with ethanol and was allowed to stand for 80 min at room temperature. A 10 mL portion of the solution and 20 mL of distilled water were mixed well and the mixture was passed through a Sep-Pak C₁₈ cartridge. The cartridge was eluted with 1.5 mL hexane and the eluate was analysed with an SE-52 fused silica column (25 m × 0.25 mm i.d.) at 130°C with an FTD. The relative retention times for aldehyde and ketone derivatives are shown in Table 5. Except for formaldehyde, acetone and di-

ethyl ketone, each derivative has syn- and anti-isomers and the double peaks appear for the isomers. The peaks of the formaldehyde, acetaldehyde, propionaldehyde and butyraldehyde derivatives were completely separated from those of the ketones. Although the first peak of propionaldehyde was not separated from the first peak of acrolein, the second peak of propionaldehyde was separated from the second peak of acrolein. Therefore, it can be judged whether the first peak of propionaldehyde contained the peak of acrolein or not. The calibration graphs obtained show good linearity over the range 0–5 µg for formaldehyde, 0–4 µg for acetaldehyde, 0–15 µg for propionaldehyde and 0–13 µg for butyraldehyde in 1 mL of the absorption solution. The determination limits ranged from 14 ppb (v/v) for formaldehyde to 67 ppb for propionaldehyde when a 30 L gas sample was used.

This method is very selective, without interference from ketones, and is well-suited to analyse simple aldehydes in various exhaust gas samples. The PFBO method was applied to analysis of carbonyl compounds in clothes, river water, seawater, tap water, indoor air samples and environmental air samples.

Thiazolidine Derivatization

Hayashi *et al.* developed a method to determine formaldehyde and methyl glyoxal in foods and beverages. This method is known as the cysteamine method. Volatile aliphatic aldehydes and ketones react with 2-aminoethanethiol (cysteamine) to form thiazolidine compound as follows:

Only one derivative is formed from each aldehyde or ketone; the reaction proceeds rapidly under mild conditions and the derivatives can be readily separated on a capillary column. The derivatives can be detected selectively with a nitrogen–phosphorus detector (NPD). Carbonyl compounds in the headspace gases above heated pork fat were analysed as thiazolidine derivatives by Yasuhara and Shibamoto (Figure 4). A GC with a 30 m × 0.25 mm i.d. DB-Wax fused silica capillary column and an NPD was used for the qualitative and quantitative analysis of the carbonyl compounds in the samples. The column temperature was held at 50°C for 2 min and then programmed to 190°C at 3°C min⁻¹. Nine aldehydes and four ketones were analysed as thiazolidine derivatives in traps containing aqueous cysteamine or

aqueous sodium bisulfite. The major compounds produced from the samples were pentanal, hexanal and heptanal. Generally, aqueous cysteamine was more efficient at trapping carbonyl compounds than was aqueous sodium bisulfite but formaldehyde and acetaldehyde were trapped better by sodium bisulfite. Acrolein and malonaldehyde were analysed as 1-methyl-2-pyrazoline and 1-methyl-pyrazole, respectively, from the trap containing methylhydrazine. Good separation of volatile aldehydes and ketones was obtained by this method.

The cysteamine derivatization method has been applied to the determination of trace amounts of carbonyl compounds in automobile exhaust, air samples, the headspace of heated food oils, foods and beverages.

Conclusion

The DNPH-GC and PFBO-GC methods are now widely used for the derivatization and gas chromatographic analysis of aldehydes and ketones. The PFBO-GC and cysteamine-GC methods will become more common. These reactions proceed under mild conditions and the derivatives are well separated with a capillary column at comparatively

low temperatures. The GC-MS measurement of these derivatives will be utilized for analysis of trace amounts of aldehydes and ketones in a variety of samples.

Introduction

Alkaloids are an important class of compounds that have pharmacological effects on the human body. These compounds can be found in natural products such as plants, and the type and amount of these alkaloids varies greatly, depending on the portion of plant analysed and the stage of maturation. Although alkaloids have traditionally been isolated from plants, an increasing number are to be found in animals, insects, marine invertebrates and microorganisms.

There is no clear definition of what constitutes an alkaloid, but these compounds do share the following characteristics: they are basic components that contain nitrogen; they are mostly complex components, derived biosynthetically from various amino acids; and they show pronounced pharmacological effects on various tissues and organs of humans and other animal species.

Pelletier defines an alkaloid as 'a cyclic compound containing nitrogen in a negative oxidation state which is of limited distribution in living organisms'. This definition includes both alkaloids with nitrogen as part of a heterocyclic system as well as the many exceptions with extracyclic bound nitrogen (**Figure 1**).

Although a wealth of information is available on the pharmacological effects of these compounds, little is known about how plants synthesize these substances or about how this synthesis is regulated. Alkaloids belong to the broad category of secondary metabolites. This class of molecule has historically been defined as a naturally occurring substance that is not vital to the organism that produces them. Alkaloids have traditionally been of interest only due to their pronounced and various physiological activities in animals and humans. A picture has now begun to emerge that alkaloids do have important ecochemical functions in the defence of the plant against pathogenic organisms and herbivores and are found to play an important role in plant interactions with animals and higher and lower plants. Alkaloids are now generally considered to be part of an elaborate system of

chemical defence in plants; indeed, the same seems to be true in vertebrates, invertebrates and microorganisms. Alkaloids have now been isolated from such diverse organisms as animals, insects, marine organisms, microorganisms and lower plants, although it is not yet clear whether *de novo* alkaloid biosynthesis occurs in each organism.

In the past ten years there has been an increasing interest in the isolation and determination of alkaloids in plant materials, in pharmaceutical products, and in other samples of biological interest. In addition, numerous alkaloids have been synthesized and chemically characterized. The active agents of around 13 000 plant species are known to have been used as drugs throughout the world. Some are used as pure compounds for therapeutic purposes (such as the narcotic and analgesic, morphine; the analgesic and antitussive, codeine; and the chemotherapeutic agents, vincristine and vinblastine) or as teas and extracts. Plant constituents have also served as models for modern synthetic drugs, such as atropine for tropicamide, quinine for chloroquine, and cocaine for procaine and tetracaine. Alkaloids can also be found in the stimulants caffeine in coffee and tea and nicotine in cigarettes. Currently, much work is being done to discover new alkaloid molecules for different applications such as new antiviral and tumour treatments.

However, many alkaloids are toxic substances and it is important to evaluate these. The vegetables Solanaceae, which contain steroidal glycoalkaloids, and Leguminosae, which contain quinolizidine alkaloids, are the principal food crops that contain alkaloids. Grain legumes are extremely important owing to their significance in human and animal nutrition. They also conserve the soil and fix nitrogen, and are used as sources of timber, fuel oils, etc. Plants of the Leguminosae rank second in economic importance only to those of the Gramineae, and the demand for legumes is likely to escalate as humans begin to utilize more marginal agricultural lands to provide food for the increased population. The largest legume subfamily is the Papilionaceae, which embraces approximately 440 genera and 12 000 species in 32 tribes, as recently reclassified by Polhill. Over 450 alkaloids have been reported to occur in plants of the Leguminosae, with the majority of such compounds occurring in papilionaceous species. Quinolizidine alkaloids (QA), contained in lupins, are the largest single group of legume alkaloids. Since lupin seeds contain

up to 50% protein and up to 20% lipids, they are of interest in terms of animal and human nutrition. *Lupinus luteus*, *L. albus* and *L. angustifolius* have

been consumed for centuries in European countries, while *L. mutabilis* (tarwi) is an important component of the South American diet.

Figure 1 Continued

This article aims to provide an overview of various aspects of separation of alkaloids by gas chromatography (GC). Although a number of phytochemical methods have been developed for the qualitative and quantitative determination of alkaloids, one of the most popular methods for the evaluation of complex alkaloid mixtures is capillary gas-liquid chromatography combined with mass spectrometry (MS). Depending on the task high performance liquid chromatography (HPLC), thin-layer chromatography (TLC), colorimetry, NMR, radioimmunoassay, capillary electrophoresis and enzyme-linked immunosorbent assay (ELISA) are additional helpful analytical techniques.

GC-MS Method for Analysis of Alkaloids

Capillary gas chromatography (CGC) analysis has been described for several classes of alkaloids. A ma-

jor advantage of GC over other methods is its enhanced sensitivity and high resolution. Another advantage is its easy coupling to a mass spectrometer, which allows the identification of new and minor compounds of a mixture without laborious isolation procedures. This makes it a particularly attractive method for thermally stable mixtures. The analysis of pyrrolizidine alkaloids, tropane alkaloids, steroidal alkaloids, quinazoline alkaloids, quinolizidine alkaloids, diterpenoid alkaloids and lycopodium alkaloids has been described by a number of authors.

Capillary gas chromatography was the method of choice and was officially accepted at the 6th International Lupin Conference in Chile (1990) as a method of determination of quinolizidine alkaloids in lupins. As an example, we will describe the methodology for the analysis of these compounds.

Sample Preparation for Chemical Analysis of Alkaloids

Successful chemical analysis of alkaloids depends on the sampling method and pretreatment of the sample. It is therefore important to know the chemistry of the compounds to be analysed. As described by Roberts and Wink, a basic character is no longer a prerequisite for an alkaloid and the chemistry of the nitrogen atom allows for at least four groups of nitrogenous compounds:

1. Secondary and tertiary amines, which are more or less protonated and therefore hydrophilic at $\text{pH} < 7.0$, or the more general case where they are lipophilic and unprotonated at $\text{pH} > 8.0$. This is the classical alkaloid type.
2. Quaternary amino compounds, which are very polar, charged at all pH values, and have to be isolated as salts, e.g. berberine and sanguinarine.
3. Neutral amino compounds, which include the amide-type alkaloids such as colchicine, capsaicin, and most lactams, e.g. ricinine.
4. *N*-oxides, which are generally highly water soluble, are frequently found in many alkaloid classes. The pyrrolizidine group of alkaloids is rich in this particular alkaloid type.

A conventional alkaloid extraction process involves successive removal of nonalkaloids and alkaloids by organic solvents from acidified and basified aqueous solutions of an ethanol extract. The extraction of alkaloids is generally based on the fact that they normally occur in the plant as salts and on their basicity, in other words on the differential solubility of the bases and salts in water and organic solvents (Figure 2).

The techniques used for sample preparation are liquid-liquid extraction, solid-phase extraction and, more recently, supercritical fluid extraction.

Liquid-liquid solvent extraction This technique is the most commonly used method for sample treatment and is based on the observation that alkaloids can usually be removed from the sample by extracting them into a water-immiscible solvent. The method relies on the relative solubility of alkaloids in the extracting solvent and the sample matrix.

Although such techniques are usually satisfactory, difficulties can be found when they are applied to chromatography where the limits of quantification are often in the ppb range. This is principally caused by the solvents being nonselective and therefore tending to extract endogenous material from the matrix, which results in spurious peaks in the chromatogram.

An example of quinolizidine alkaloid liquid-liquid extraction is provided in Figure 3.

Solid-phase extraction for sample preparation

Sample clean-up is required when impurities in the sample matrix interfere with analyte measurement. The interest in this technique led to the commercial introduction of small disposable cartridges packed with relatively large particles of various bonded silicas. The particle size allows the use of minimum pressure to force the sample and wash solutions through the column. Indeed, it is common practice to suck the solution through the packings rather than to use pressure.

There are many advantages of solid-phase extraction including: (1) the possible use of large sample sizes in pretreatment; (2) the technique is quick and automated; (3) the low consumption of solvents used; (4) the use of selective sorbents and solvents; (5) the possible achievement of a high pre-concentration of the component of interest, enabling high sensitivities to be obtained; (6) there is good reproducibility in GC; and (7) the technique is inexpensive.

In developing assays using solid-phase extraction, it is necessary to take into account several factors when deciding on the choice of sorbent to be used in a particular assay for alkaloid analysis.

The most important consideration of the technique is that the compounds of interest must be capable of being readily absorbed from the matrix. In some cases, pretreatment of the sample is necessary, especially in cases of protein binding. This can usually be solved by the addition of perchloric or trichloroacetic acid to denature the proteins. In addition, it may be necessary to adjust the pH of the sample to ensure that the compound is in the correct ionic form to achieve efficient retention by the packing. Proteins can also be removed by the addition of organic solvents such as acetonitrile or methanol.

After removing the majority of the interfering substances, the final step of the technique is efficient elution from the bonded silica. This step must ensure that the compounds of interest are desorbed in the least volume of eluent, since it is usual to evaporate the solution to dryness and reconstitute the residue in a small volume prior to chromatographic analysis. The evaporation step generally precludes the use of inorganic salts in the final wash solution, with the exception of those compounds that are readily volatile.

Quinolizidine alkaloid solid-phase extraction is illustrated in Figure 4.

Analytical supercritical fluid extraction At present, and in view of increasing environmental concerns of

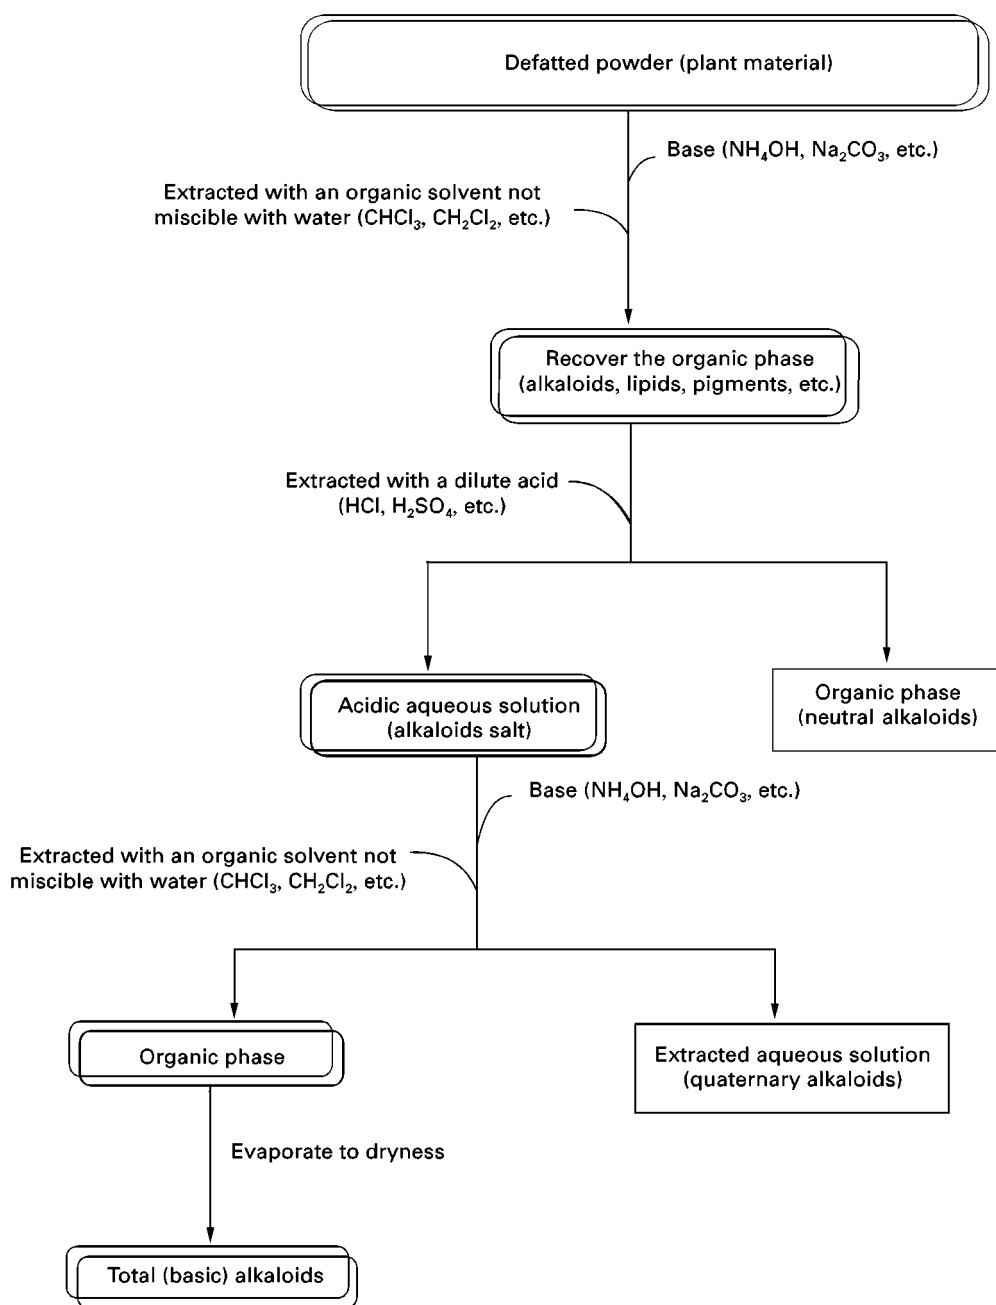

Figure 2 Extraction of alkaloids.

the use of liquid solvents in the extraction of natural products, there has been growing interest in alternative and reliable sample extraction techniques using supercritical fluids. Supercritical fluids have been widely used for the extraction of alkaloids on both analytical and industrial scales and for many years for the selective extraction of selected compounds from bulk samples. The extraction of caffeine from coffee is a well-known process performed on an industrial scale. The aim here is to remove a specific component

(i.e. caffeine) from large quantities of the bulk matrix in order to increase its commercial value.

Analytical-scale supercritical fluid extraction (SFE) is concerned more with extraction of analytes of interest from a bulk matrix as a sample preparation step prior to characterization by other analytical methods such as GC. It is therefore potentially very useful for the extraction of natural products prior to structural characterization. SFE is gaining acceptance as an alternative to Soxhlet extraction. Much of the

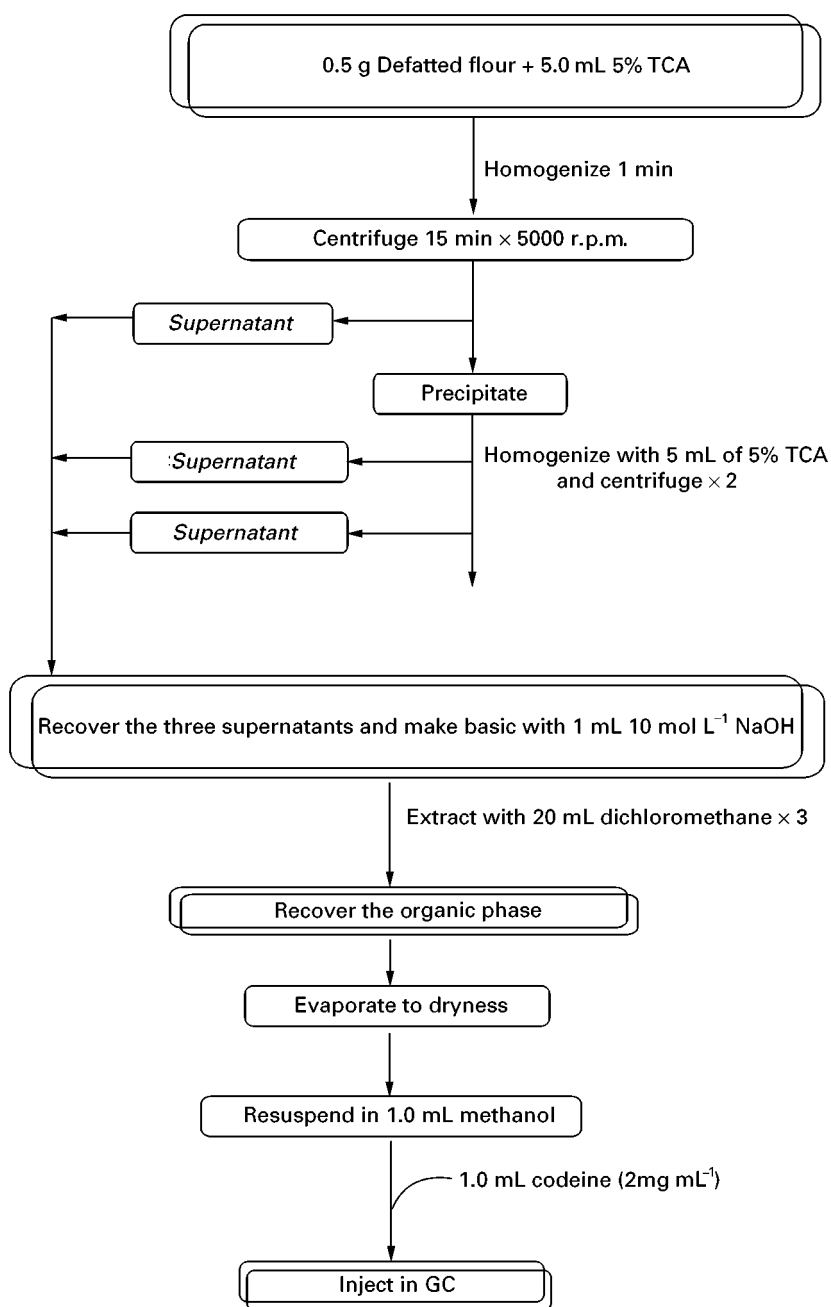

Figure 3 Extraction of quinolizidine alkaloids (Muzquiz *et al.* 1994).

current interest in using analytical-scale SFE stems from the need to replace conventional liquid extraction methods with sample preparation methods that are more efficient, easier to automate, faster and safer to use. Many of the properties of supercritical fluids such as carbon dioxide have facilitated advances in these areas. Thermally labile compounds can be extracted at low temperatures and greatly reduced extraction times. Extracts can also be analysed online by coupling the SFE directly with a gas chromatograph (SFE-GC).

Determination of Alkaloids by Gas-Liquid Chromatography-Mass Spectrometry

Methods for the unequivocal identification and quantification of alkaloids in various, often complex, matrices are of great interest. For this purpose chromatography is widely used. Originally thin-layer chromatography (TLC) was the major method applied for both qualitative and quantitative analysis of alkaloids. Although TLC is still a major tool in alkaloid analysis, in recent years high performance liquid

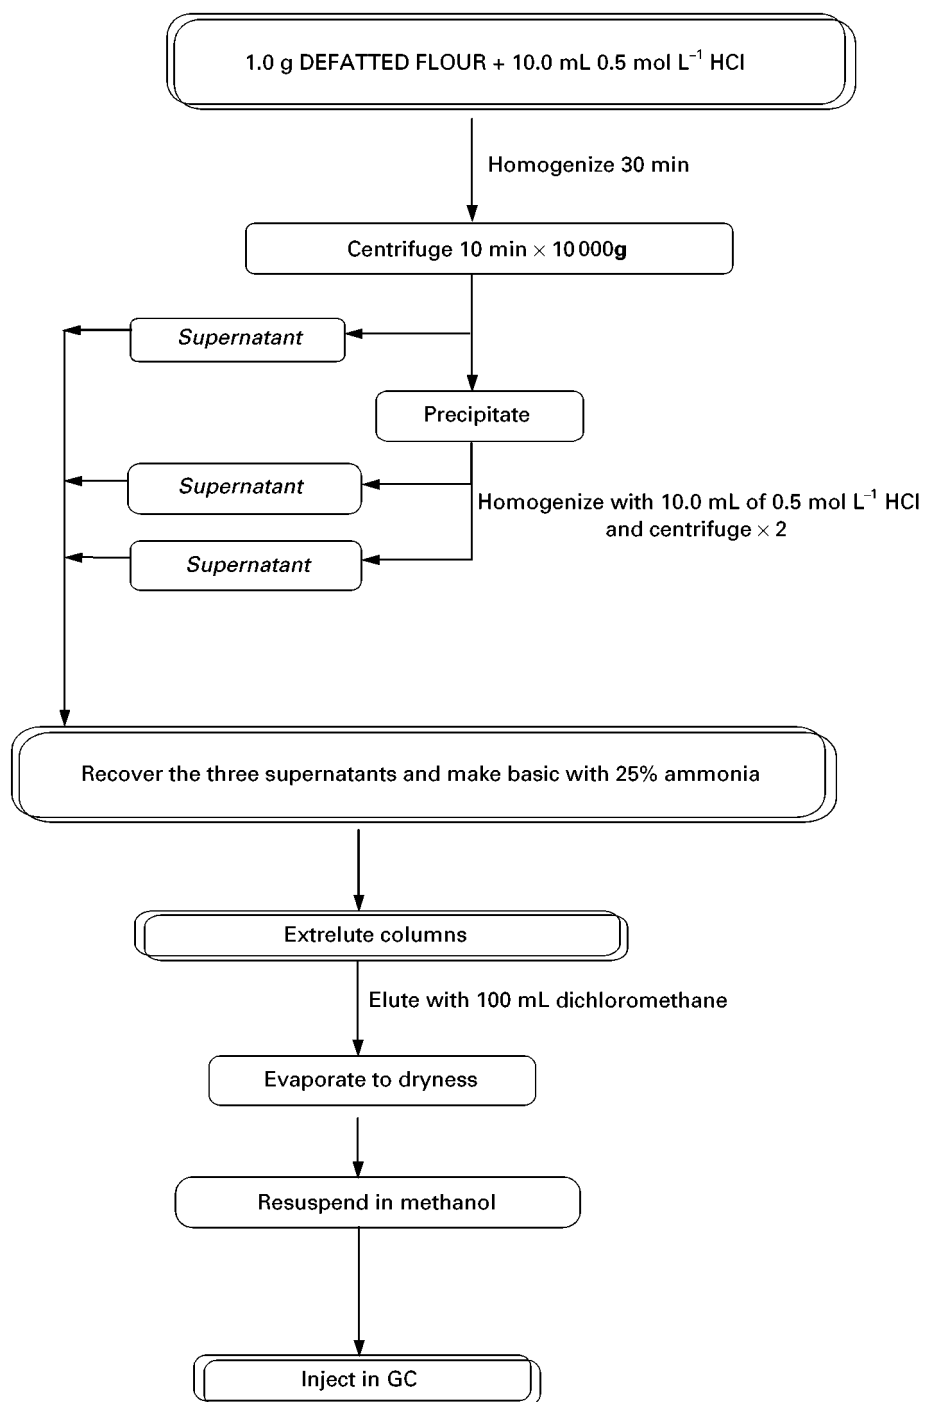

Figure 4 Extraction of quinolizidine alkaloids (Wink *et al.* 1995).

chromatography (HPLC) has also developed as an important method for the quantitation of alkaloids. However, more and more applications of capillary (CGC) for complex alkaloids have been reported recently.

Combined gas chromatography-mass spectrometry (GC-MS) has been increasingly used over the

last decade for the convenient analysis of alkaloids. This sensitive technique is applicable to the qualitative analysis of individual components of crude alkaloid fractions and is normally able to resolve alkaloid diastereoisomeric pairs. GC-MS is particularly suitable for work of a chemotaxonomic nature, since in such studies it is desirable to identify all the alkaloids

that may have accumulated at a specific time and site in a specific part of a species, rather than only the most abundant compounds present. Also, the use of GC-MS may enable the experimenter to rule out the presence of a particular alkaloid group in the plant material being examined. Impressive separations of alkaloids have been obtained using the high column efficiencies achieved in CGC.

Until 1980 most GLC applications for separating alkaloid mixtures involved packed columns. However, better results can be obtained using the new generation of fused silica capillary columns with bonded phases. The advantage of using small internal diameter columns is not only the higher plate number per unit length, but also the improved lower level of detection due to reduced band broadening. Much more important than efficiency however, is the selectivity that can be introduced into the chromatographic system. The reason for this is that even the best capillary column still has a limited peak capacity (maximum 1000), which is certainly insufficient for unravelling the complex profiles that have to be dealt with in natural product research.

Some GC systems used for the analysis of alkaloids are indicated in Table 1. The column selectivity can be adapted to the specific problem by selecting the most suitable stationary phase. Stationary phase selection, however, has no influence on the peak capacity. In addition to universal inlets such a split, splitless, cool on-column and temperature-programmed vaporization, a number of selective inlets are available in CGC.

In the case of QA the capillary columns used (dimensions 15 m \times 0.23 mm to 30 m \times 0.32 mm) have a high number of theoretical plates ($> 70\,000$), which allow the separation of complex mixtures and even of enantiomers, epimeric at C11 or C6, such as sparteine and α -isosparteine, lupanine and α -

isolupanine, 13-hydroxylupanine and 23-epihydroxylupanine, anagyrine and thermopsine, 13 α -tigloyloxylupanine and 13 β -tigloyloxylupanine, and of *cis* and *trans* isomers, such as 13 α -angeloyloxylupanine and 13 α -tigloyloxylupanine, as well as the *trans*- and *cis*-cinnamic acid esters.

As a liquid phase several silicone derivatives (0.1 μ m or 1 μ m films) are employed; good resolutions have been obtained using DB-1 or DB-5 columns, but equivalent products of other manufacturers also work. Split injection techniques are usually appropriate. On-column injection does not provide significant advantages for most applications.

Helium is routinely used as carrier gas, but hydrogen or nitrogen will also work. The injector temperature is usually set at 250°C, that of the detectors at 300°C. Furthermore, even nanogram amounts of alkaloids can be detected by the FID (flame ionization detector) or more sensitively and specifically by a nitrogen-specific detector (NPD).

Hydroxylated QA, such as 13-hydroxylupanine or 3-hydroxylupanine, may be derivatized by trimethylsilyl prior to injection to avoid tailing and to achieve better quantification. Care should be taken not to use the NPD for these derivatives, since the detector would soon be destroyed.

Some authors give relative retention indices for QA. However, Kováts retention indices (RI) give better comparative information and are helpful in identifying individual alkaloids in a GC profile.

Additionally, since this method can be combined with mass spectrometry (GC-MS) it is easy to identify the individual compounds present. Among the spectroscopic methods, mass spectroscopy is definitely the most powerful technique and should therefore take an important place in any laboratory. The problems of interfacing both techniques have been completely

Table 1 Some GC systems used for the analysis of alkaloids

Alkaloid	Column type, length (m) \times i.d. (mm)	GC conditions			Carrier gas
		Injector	Temperature program (°C)	Detector	
Pyrrolizidine	WCOT DB-1 25 m \times 0.25 mm	250°C	120–290 (8°C min ⁻¹)	FID, NPD	He

WCOT, Wall coated open tubular column.

overcome by direct coupling (no interface) or the use of an open split interface. Low and high resolution mass spectrometers are the most universal detection devices for CGC. They are capable of electron impact

or chemical ionization and can be operated in the full scan mode for identification of unknowns or in the ion-monitoring mode for quantification of target compounds.

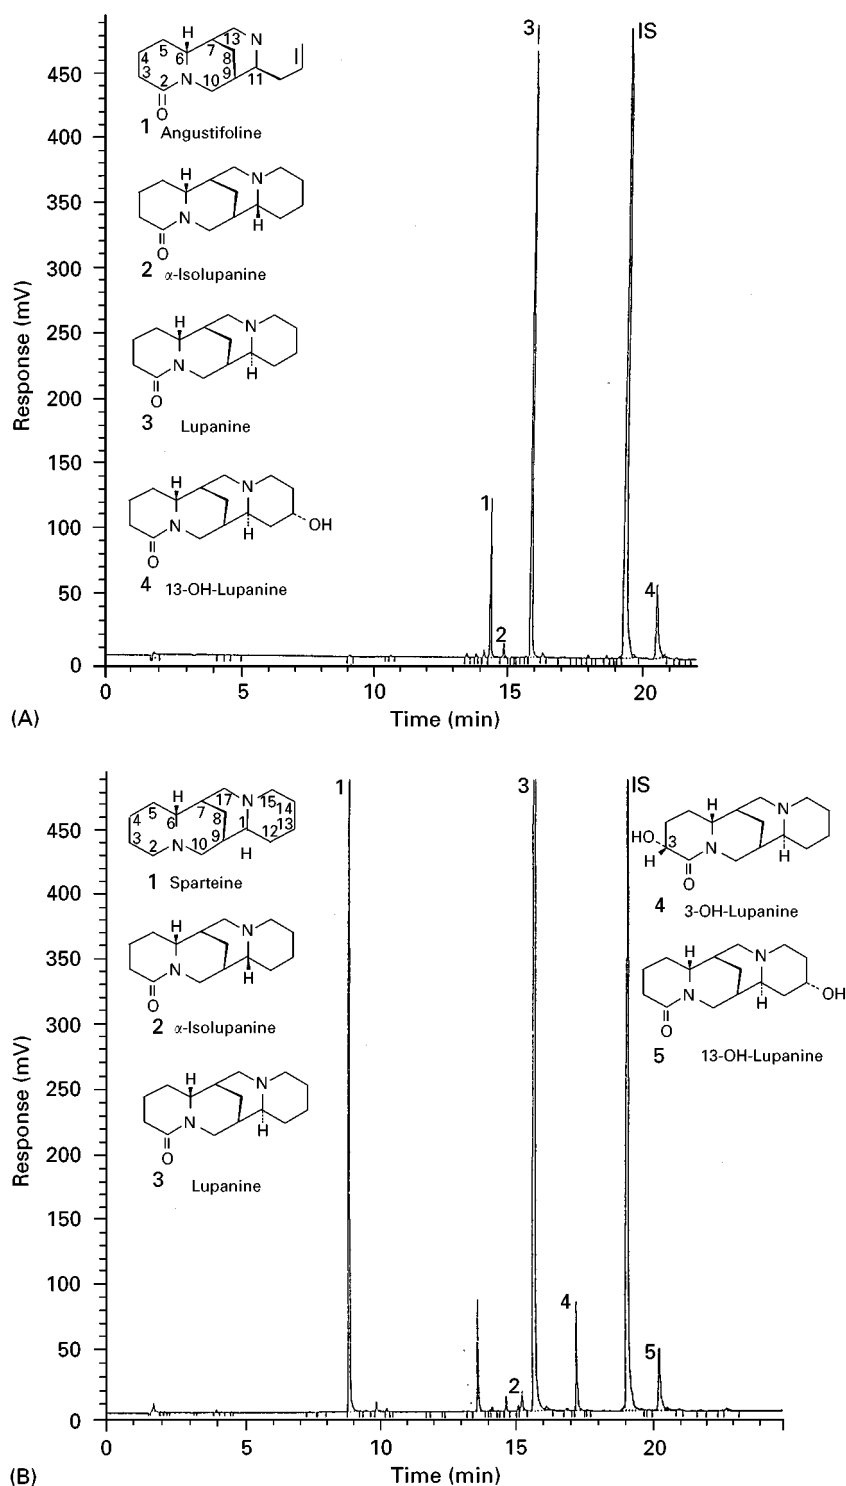

Figure 5 Separation of an alkaloid extract from *L. angustifolius* (A) and *L. mutabilis* (B) bitter seeds by capillary GC. Injector, 240°C; detector 300°C; oven 150–235°C, 5°C min⁻¹; carrier gas, helium; detection of alkaloids by nitrogen-specific detector (NPD) and mass-selective detector.

Mass spectrometry is widely used today, since QA usually provide distinctive fragmentation patterns in the electron impact mode (EI-MS). Chemical

ionization (CI-MS), field desorption (FD-MS) and fast atom bombardment (FAB-MS) are suitable for identifying molecular ions of QA esters and of

Figure 6 Separation of an alkaloid extract from *L. luteus* (A) and *L. hispanicus* (B) bitter seeds by capillary GC. Injector, 240°C; detector 300°C; oven 150–235°C, 5°C min⁻¹; carrier gas, helium; detection of alkaloids by nitrogen-specific detector (NPD) and mass-selective detector.

tricyclic alkaloids, whose molecular ions are usually obscure or absent in EI-MS spectra. A major advantage of MS is the possibility it gives of combining the high resolution power of capillary GC with the sensitivity of and information provided by EI- or CI-MS. Work using GC-MS was very much facilitated after 1980 by the development of new GC capillary columns, the development of new methods to position the GC column exit near the MS ion source and, most importantly, by improved data processing.

Alkaloid extracts of many legumes contain piperidine alkaloids such as ammodendrine, *N*-methylammodendrine, hystrine or smipine. These alkaloids also derive biogenically from lysine via cadaverine. Simple indole and quinolizidine alkaloids, such as gramine and lupanine may also be encountered. Even combinations of both indole and quinolizidine units are possible, as in the case of *Lupinus hispanicus*.

Separation and identification of QA by GC-MS is shown in Figures 5–7.

Conclusion and Future Developments

Gas chromatography is a versatile tool in the analysis of natural products with a wide area of application. It

is capable of extracting a wide range of diverse compounds from a variety of sample matrices.

Clear advantages of GC are the high sensitivity of the most common detection method, the FID, and the fact that the detector response of similar compounds will be about the same (i.e. peak areas may be directly compared for quantification). By using a nitrogen-specific detector (NPD) sensitivity for alkaloids can be even further improved while at the same time introducing selectivity.

No systematic studies to determine which column is best suited for alkaloid analysis have been reported, but from the methods described to date it is clear that thinly coated apolar columns are preferred for the analysis of underivatized alkaloids. The length of the columns used varies considerably and it is advisable to test the stability of a compound under GC conditions with a short column. A longer column may be used later if the desired chromatographic resolution has not been achieved.

A wealth of information can be obtained by the analysis of alkaloids by GC coupling to MS. Coupled techniques (GC-MS) have demonstrated their analytical potential. The large amounts of data produced by capillary GC, especially when coupled to a mass spectrometer, can now be handled by a personal

Figure 7 Separation of alkaloid extracts from *Chamaecytisus proliferus* by capillary GC. Injector, 240°C; detector 300°C; oven 150–235°C, 5°C min⁻¹; carrier gas, helium; detection of alkaloids by nitrogen-specific detector (NPD) and mass-selective detector.

computer. The data can be acquired, manipulated and displayed in real time and can be stored for record purposes.

Looking to the future, it is reasonable to expect continued evolutionary development: new selective detectors, more complex analysers for automated sample processing, increasing use of coupled techniques, columns with immobilized phases of a wider range of selectivity, etc. It is hoped that further research and development will encourage the use of GC-MS in the areas of alkaloid analysis that still await investigation.

Definition and Classification of Alkaloids

Alkaloids represent a wide variety of chemical structures (Figure 1). More than 16 000 are known and most

are derived from higher plants. Alkaloids have also been isolated from microorganisms, marine organisms like algae, dinoflagellates and puffer fish and terrestrial animals like insects, salamanders and toads.

An alkaloid has been defined by Pelletier as a cyclic organic compound containing nitrogen in a negative oxidation state which is of limited distribution among living organisms. From the analytical chemical point of view, the most important trait of alkaloids is their

basicity arising from a heterocyclic tertiary nitrogen atom. Notable exceptions are colchicine and the xanthines (e.g. caffeine), with pK_a values between 1 and 2. Alkaloids are biosynthetically derived from

amino acids, such as phenylalanine, tyrosine, tryptophan, ornithine and lysine. The biogenesis of alkaloids is used for their classification, as this is directly linked with their molecular skeleton, e.g. the two

Noscapine	
Papaverine	
Sanguinarine	
Thebaine	
Tubocurarine	

largest groups are indole alkaloids (more than 4100 compounds) and isoquinoline alkaloids (more than 4000 compounds). Other important groups are tropane alkaloids (*c.* 300 compounds), steroidal alkaloids (*c.* 450 compounds), pyridine and pyrrolizidine alkaloids (about 250 and 570 compounds, respectively).

The botanical origin of the alkaloids is also used as a classification method, e.g. *Papaver* (opium) alkaloids, *Cinchona* alkaloids, *Rauvolfia* alkaloids, *Catharanthus* alkaloids, *Strychnos* alkaloids, ergot alkaloids, cactus alkaloids and *Solanum* alkaloids. As secondary metabolites, alkaloids probably play a role in defending organisms against pests and

diseases. For example, for some types of alkaloids, insect antifeedant activity has been established. Thus, many alkaloids have strong biological activities. Their effect in humans can be explained by structural relationships with important signal compounds (neuro-transmitters) like dopamine, acetylcholine, noradrenaline and serotonin. Consequently, some alkaloids are used as medicines or in pharmacological studies (Table 1). In addition to pure compounds, crude plant extracts containing alkaloids are used (phytotherapy). Another area where alkaloids play a major role is in drugs of abuse, e.g. mescaline, cocaine, morphine and its semisynthetic derivative, heroin. Alkaloids are also of interest in the analysis of doping (e.g. strychnine, ephedrine, caffeine) and poisons (e.g. strychnine, pyrrolizidine alkaloids, coniine, nicotine, aconitine, tetrodotoxin).

Due to their various applications, the analysis of alkaloids is of great importance. The very different types of (ab)use of the alkaloids mean that the type of analyses also varies. Alkaloids must be analysed in a broad variety of matrices, such as plant material, tablets, drug seizures, urine and blood. Each requires different sample clean-up methods and chromatographic selectivities. Liquid chromatography is the most commonly used method since the instability and low volatility of alkaloids mean that gas chromatography has a limited applicability. Because the extracts are often complex and 'dirty', thin-layer chromatography is useful in analysing alkaloid-containing plant extracts.

Chemical Properties and Artefact Formation

Most alkaloids have basic properties with pK_a values of about 6 to 12, but usually 7–9. The free base is soluble in organic solvents and not in water. Protonation of the nitrogen in the free base usually results in a water-soluble compound. This behaviour is the basis of the selective isolation of alkaloids by liquid/liquid partitioning processes. Quaternary alkaloids are poorly soluble in organic solvents but soluble in water at any pH.

Many alkaloids are difficult to crystallize in the form of the free base, but do crystallize as a salt. Alkaloids are usually colourless; only some highly conjugated compounds are coloured or show strong fluorescence (e.g. berberine and serpentine).

Alkaloids are not very stable; in particular, N-oxidation is quite common. Stability is influenced by solvents, as well as heat and light. Halogen-containing organic solvents such as chloroform and dichloromethane are widely used in alkaloid research.

Chloroform in particular is a very suitable solvent, because of its relatively strong proton donor character. However, this solvent easily causes the formation of artefacts, e.g. (*N*-)oxidation occurs easily. Dichloromethane may result in the formation of quaternary *N*-dichlorometho-compounds. Similar compounds are formed with the minor impurities present in chloroform. Peroxides in ethers may also cause *N*-oxidation.

Alkaloids are more stable in toluene, ethyl acetate and alcoholic solutions. Carbinolamine functions are often found in alkaloids, either formed during the coupling of a carbonyl group and an amine in the biosynthesis, or as products formed from rearrangements of *N*-oxides. Carbinolamines readily react with alcohols (e.g. *O*-methyl pseudostrychnine formed from pseudostrychnine with methanol). Ketones such as acetone and methylethylketone are well-known artefact formers. Berberine, for example, may react with acetone. Ammonia and acetone may react during column chromatography, yielding condensates that give a Dragendorff-positive reaction. Ammonia may also react with aldehydes present in plant materials, giving rise to artificial alkaloids, e.g. the pyridine-type alkaloid gentianine is formed from sweroside during extraction.

Extraction

Due to the more lipophylic character of alkaloids as free bases, they can be extracted under neutral or basic conditions (e.g. after basification of the plant material or biofluid to pH 7–9 with ammonia, sodium carbonate or sodium bicarbonate) with organic solvents (such as dichloromethane, chloroform, ethers, ethyl acetate and alcohols). Strongly basic alkaloids can only be completely extracted at higher pH (>10), e.g. tryptamine. As a general rule of thumb, for the extraction of an alkaloid one should choose a pH of $pK_a + 2$. On the other hand, alkaloids containing phenolic groups are protonated at higher pH, and thus not extracted by organic solvents under such conditions (e.g. morphine).

Alkaloids can be extracted in protonated form (after acidification to pH 2–4 with diluted acids like phosphoric acid, sulfuric acid, citric acid) with water or alcohols (e.g. methanol).

Alkaloids can be further purified by liquid–liquid extraction or liquid/solid extraction. In liquid–liquid extraction the alkaloids are, after basification, extracted from an aqueous solution with an immiscible organic solvent or from an organic solvent with an aqueous acid solution. To avoid the formation of lipophylic ion pairs, phosphoric acid, sulfuric acid and citric acid are preferred over acetic acid and

hydrochloric acid. By using a back-extraction from aqueous solution to organic and back to aqueous, or from organic to aqueous and back to organic solution, alkaloids can easily be separated from neutral and acidic compounds.

Alkaloids can be extracted from acidic aqueous solutions with organic solvents by using ion-pairing reagents (e.g. alkylsulfonic acids). It should be noted that common anions such as Cl^- , Br^- , I^- and acetate also form ion pairs which are readily soluble in organic solvents.

Solid-phase extraction using adsorption or ion exchange can also be used. For adsorption of the alkaloids in the free form, reversed-phase materials, such as chemically bonded C_8 and C_{18} on silica, are widely used. A suitable solvent system is a mixture of methanol and water; the crude extract is fractionated by stepwise elution of the adsorbent with a solvent of decreasing polarity. XAD-2 is also used for the concentration of alkaloids, e.g. from biological fluids. Various cation exchange materials can be used for the selective extraction of alkaloids.

For preparative purposes purifications based on the precipitation of alkaloids are employed. A crude extract of the alkaloids is made with aqueous acid; subsequently the alkaloids are precipitated with reagents such as Mayer's reagent (1 mol L^{-1} mercury chloride in 5% aqueous potassium iodide) or Reinecke's salt (5% ammonium reineckate in 30% acetic acid) at pH 2, or picric acid (saturated aqueous solution) at pH 5–6. After collection by filtration or centrifugation, the precipitate is dissolved in an organic solvent (acetone:methanol:water; 6:2:1). The complexing group is then removed by means of an anion exchanger. Quaternary alkaloids cannot be purified by means of liquid–liquid extraction, therefore precipitation is particularly suited for their purification.

Thin-layer Chromatography

Thin-layer chromatography (TLC) is widely used as a versatile method in the analysis of alkaloids. It offers the advantage of a broad range of polarities being separated in one single analysis, which is of interest in plant materials and metabolism studies. The most widely used stationary phase is silica; alumina plates are rarely employed nowadays. Reversed-phase materials, such as chemically bonded C_{18} on silica, are also applied but silica is still used most widely.

Strongly basic alkaloids will show severe tailing on silica gel plates, due to the acidic properties of silica. The use of mobile phases which contain

Table 2 Some common thin-layer chromatography systems for the analysis of alkaloids

<i>Solvent system (all with silica plates)</i>	<i>Commonly used ratios</i>	<i>Polarity range</i>

lp, Low polarity compounds; mp, medium polarity compounds; p, polar compounds; wb, weakly basic compounds.

a base such as ammonia or diethylamine will overcome this problem. A more elaborate method is the use of TLC plates impregnated with a basic solution.

For the analysis of highly polar quaternary alkaloids and *N*-oxides, solvent systems consisting of methanol and aqueous salt solutions are useful. In Table 2 some widely used TLC systems are summarized. For the detection of alkaloids a large number of methods have been reported. Besides quenching ultraviolet (UV) light on fluorescent plates and fluorescence, general reagents for selectively detecting alkaloids are Dragendorff's reagent (orange-brown spots) and potassium iodoplatinate (brown-violet-purple spots; Table 3). Dragendorff's reagent may cause false-positive reactions with, for example, compounds containing conjugated carbonyl or lactone functions. The iodoplatinate reagent has less risk of false-positive reactions and is more selective due to a broader spectrum of colours observed for individual alkaloids.

Highly selective reagents have been reported for the visualization of various classes alkaloids (Table 4). These are based on different colorations under strongly oxidative conditions.

Liquid Chromatography

High performance liquid chromatography (HPLC) is a major tool for the analysis of alkaloids. Most separations are done on reversed-phase (RP) materials (C₈-, C₁₈- and phenyl-bonded phases on silica). Although extensive tailing due to the interaction of the basic nitrogen and residual acidic silanol groups may occur on the RP materials. In particular, strong bases show this problem. Several solutions have been found

to circumvent this. First, special RP materials have been developed for basic compounds. These materials have an altered silica surface, a high load of the alkyl groups or they have undergone a rigorous endcapping treatment to reduce the number of free silanol groups. Often the plate numbers observed for alkaloids on an HPLC column are considerably lower than those measured with the usual neutral test compounds. Polymeric (e.g. polystyrene-based) stationary phases do not have the problem of residual silanol groups; however, plate numbers observed with such columns are not usually better than those found with specially made RP silica materials. Phenyl-type RP columns are also successful in the separation of alkaloids.

Another way of reducing the tailing is through modification of the eluent. By adding long chain alkylamines (e.g. hexylamine) in low concentrations

Table 3 Detection reagents for alkaloids on thin-layer chromatography plates

<i>Dragendorff's reagent (modification according to Munier)</i>
(A) 1.7% bismuth subnitrate in 20% aq. tartaric acid solution
(B) 40% potassium iodide in water
A and B are mixed (5 : 2) and the spray reagent is prepared by mixing 50 mL of the stock solution with 100 g tartaric acid and 500 mL water.
Colours observed after spraying: orange-brown spots for alkaloids
<i>Potassium iodoplatinate reagent</i>
The reagent is prepared freshly by mixing 3 mL of 10% aq. hexachloroplatinic acid solution with 97 mL water and 100 mL of 6% aqueous potassium iodide solution.
Colours observed after spraying: brown-violet-purple spots for alkaloids

Table 4 Selective colour reactions for the detection of alkaloids on thin-layer chromatography plates

<i>Spray reagent</i>	<i>Commonly used for the detection of</i>
0.2 mol L ⁻¹ ferric chloride in 35% perchloric acid and heat	Indole alkaloids, isoquinoline alkaloids
1% ceric sulfate in 10% sulfuric acid	Indole alkaloids
1% <i>p</i> -dimethylaminobenzaldehyde in ethanol, followed by exposure to hydrochloric acid vapour	Ergot alkaloids
Sulfuric acid and heat	Various alkaloids

(typically 1 mmol L⁻¹) to the mobile phase, tailing can be considerably reduced. Also, addition of amines like triethylamine or tetramethylammonium can be helpful in reducing tailing. Moreover, alkaloids have been analysed on aminopropyl- and cyanopropyl-type of columns, in both normal and reversed-phase modes.

In liquid chromatography of alkaloids, the pH of the mobile phase must be strictly controlled, as stationary phases are unstable at a pH above 8, usually a pH between 2 and 4 is used, i.e. the alkaloids are present in the protonated form. Ion suppression systems are quite common. Because of the preference for the lower pH range of the eluent, ion pairing is used with C₄–C₈ alkylsulfonates at a concentration of 25–100 mmol L⁻¹ for the analysis of alkaloids. Increasing length of the alkyl chain causes longer retention.

Some general features of RP HPLC systems for the analysis of alkaloids are given in Table 5.

The number of applications of ion exchange chromatography for the separation of alkaloids is limited. In general, cation exchange columns will also affect the selectivity of the separation through nonionic interactions, e.g. through the stationary phase matrix. Usually an elevated temperature is used to improve peak shape.

A large number of liquid–solid separations on silica have been reported (Table 6). The systems applied are similar to those reported for TLC.

UV is most widely used for detection. Particularly for the groups of indole and isoquinoline alkaloids,

strong and specific UV chromophores are found. These can greatly assist in identifying compounds, e.g. in using HPLC with diode array detection. The pH of the solvent as well as the solvent itself may have an effect on the UV spectra, e.g. causing shifts of maxima and minima. Some alkaloids can be detected by means of their fluorescence. Some type of alkaloids have poor UV absorption properties, e.g. tropane alkaloids, pyrrolizidine alkaloids and steroidal alkaloids require detection at lower wavelengths (200–220 nm). Electrochemical detection has been applied, enabling the selective attenuation of interfering compounds. Mass spectrometry is a major tool in the identification and structure elucidation of alkaloids. In combination with gas chromatography and liquid chromatography, it is very useful in the qualitative and quantitative analysis of complex mixtures of alkaloids. Solvent systems suited for liquid chromatography–mass spectrometry should only contain volatile compounds (e.g. ammonium acetate, ammonium formate).

Countercurrent Chromatography

The preparative isolation of alkaloids can be achieved by means of modern countercurrent chromatography. Because of the ionic nature of the alkaloid systems with a controlled pH are preferred for the separation. Improved efficiency can be obtained by using ion pair gradients, e.g. solvent two-phase systems consisting of chloroform–methanol–aqueous

Thin-Layer (Planar) Chromatography

J. Flieger, Medical Academy, Lublin, Poland

Copyright © 2000 Academic Press

Introduction

In 1938, Izmailow and Schraiber pioneered the thin-layer chromatography (TLC) method for the analysis of plant material containing alkaloids. The subject matter of their scientific research was an extract of a plant rich in tropane alkaloids. Later on, the method was developed by Bekesy, who applied it to the separation of ergot alkaloids. Since then, numerous papers exploring the detection, isolation and quantitative determination of alkaloids by TLC have been pub-

lished. It has been stated that no other method has delivered so much information on alkaloids.

From the chemical point of view, alkaloids form a very diverse group of organic nitrogen compounds of a basic character (with the exception of some derivatives of purine and colchicine). They have tertiary or quaternary amino groups in their molecules and only a few contain secondary amino groups. Considering the fact that analytical problems connected with alkaloids are mostly concerned with their physicochemical properties, they are commonly divided according to the type of chemical structure into tropane, quinoline, indole, diterpene and others. Another useful classification is based on botanical groups (e.g. tobacco, lupine, ergot, strychnos, vinca and catharanthus alkaloids), and this is

especially valuable as far as chemotaxonomical studies are concerned.

In early work, alkaloids were predominantly isolated from the natural plant material. TLC was then used for qualitative and quantitative analysis of plants and the study of the biosynthesis of alkaloids. Because of their powerful physiological properties alkaloids have become important therapeutic compounds and many of them have been prepared synthetically or by partial synthesis. As a consequence, many derivatives have been formed that do not occur in nature. TLC is particularly well suited for checking the processes of synthesis as well as for establishing the progress of reactions and finally testing of products in pharmaceutical preparations. The importance of alkaloids is also fundamental in toxicological analysis; many are used as narcotics and hallucinogenic drugs, as doping substances and as poisons. The presence of alkaloids in drugs of abuse and their metabolites in biological fluids such as urine and blood has also been tested by means of TLC.

Preparation of Samples

Various sample preparation procedures have been developed for pharmaceutical formulations, plant and biological materials. Due to the fact that, in most of them, alkaloids occur as salts together with complex mixtures of nonalkaloid compounds such as inorganic salts or substances of lipophilic character, their pre-separation by a suitable extraction procedure is necessary.

While in the case of the analysis of solutions, alkalinized (or acidified) samples and extraction with an organic solvent such as chloroform or diethyl ether is usually sufficient, isolating alkaloids from a plant material is a multistage process and may be conducted using several methods.

Most often preparative isolation is carried out by liquid-liquid extraction. Plant material with a high liquid content should be initially extracted with light petroleum or water containing diluted hydrochloric acid to remove lipids. The release of alkaloidal bases occurs under the influence of the addition of a mineral base, commonly ammonia. Then they are extracted by means of water-immiscible organic solvents or water-alcohol mixtures.

For efficient extraction in the above cases described, alkaloids should be present in the extractable form in at least 95%, so pH adjustment of the sample to $\text{pH} = \text{pK}_a + 2$ is sufficient.

Further purification is achieved by re-extracting alkaloids from organic solvents into an aqueous phase of the opposite pH, where the alkaloids are present as salts.

Figure 1 Scheme for the back-extraction procedure of a basic drug (B) (after Adamovics JA (1990) *Chromatographic Analysis of Pharmaceuticals*. New York and Basel: Marcel Dekker, Inc.)

This back-extraction procedure for basic compounds (B) is shown schematically in **Figure 1**.

A liquid extraction technique used to increase extraction efficiency and selectivity is an ion pair extraction originally used to extract strychnine from syrup.

Purification of crude plant extracts from non alkaloidal compounds may be carried out by precipitating the alkaloids with picric acid, Reinecke's salt or Mayer's reagent or by using ion exchange or a small adsorption column. Solid-phase extraction (SPE) is gaining in popularity. Specific sorption conditions under which alkaloids are strongly retained lead to preconcentration of free bases (on aluminium oxide), their salts (on phosphoric acid impregnated silica) or as an ionic form (on ion exchangers).

It should be emphasized that, in the case of silica gel, quaternary alkaloids are more strongly retained than ternary ones with an aqueous buffer-methanol mobile phase. Such differences also create the possibility of separating these two groups of alkaloids.

One of the latest methods of isolating groups of alkaloids from solid samples is supercritical fluid extraction (SFE). The method increases the efficiency of extraction and shortens the overall time of analysis.

While considering the problems of extraction, isolation and purification of alkaloids, one should be cautious about the possibility of undesirable reactions and artefact formation. One reason may be impurities present in the solvents applied. Thus, peroxides (in ethers) cause oxidation, ethyl chloroformate (in chloroform) forms ethylcarbamates of alkaloids; halogen-containing compounds; bromochloromethane and dichloromethane (in chloroform) cause quaternization of tertiary alkaloids, while cyanogen

chloride (in dichloromethane) is the cause of nitrilation of primary and secondary amines. Decomposition may also be caused by a photochemical reaction, especially in chloroform solutions. Finally there may be a reaction with a solvent itself, mainly with chloroform, but also with ketones or strong alkali. The fact that the chloroform used as a component of the mobile phase may present a quenching effect should also be emphasized.

Development Techniques

Adsorbents used in TLC may be either commercial products or home-made plates (now seldom employed). High quality chromatograms can be achieved with HPTLC plates which were introduced in the 1980s.

Plates may be developed in a linear, circular or anticircular mode. The most common technique in TLC of alkaloids is ascending, single, one-dimensional development in tanks saturated with the vapour of the solvent system.

Preconditioning the plate with the vapours, thus preventing demixing of the mobile-phase components, can also be performed in sandwich-type chambers produced by Camag (Vario-KS) and Chromdes (DS). In some cases, especially where compounds differ in polarity, repeated development of the plate with the same solvent or solvents of increasing strength or the continuous development technique has some advantages. In other cases, programmed multiple development with the same solvent may be successfully applied. Also useful is two-dimensional development, which is especially valuable for separating a greater number of alkaloids in a given section of the plate.

Great differences in the polarity of alkaloid molecules make gradient elution advantageous. This technique may be developed in both glass chambers and in horizontal chambers as well as with overpressured layer chromatography.

Worth noticing is one technique related to TLC – thin-layer electrophoresis, which has been used as a two-dimensional combination with TLC for the separation of ergot alkaloids.

Separation Methods

It is obvious that the kind of adsorbent used and solvent system composition determine the separation mechanism occurring in the chromatographic process. The adsorbent also determines the method of sample preparation. Thus, for adsorption and partition chromatography, alkaloids are mostly applied as bases in organic polar solvents; for ion exchange

sorbents they are applied in the form of salts in aqueous solution.

Choosing the optimal chemical character of the stationary and mobile phase is especially important in the case of alkaloids because of the ionization ability of their molecules. Dissociation of bases in aqueous solution can be expressed by the following equation:

or, in the case of the conjugated acid BH^+ , by:

with a dissociation constant (acidic) K_a .

The dependence of the molar ratio of nondissociated molecules $[B]$ to the total concentration of an alkaloid $[B] + [BH^+]$ on the pH of the mobile phase is shown in the curves presented in Figure 2. The pK_a values of chosen alkaloids are summarized in Table 1.

For TLC of alkaloids, numerous chromatographic systems have been reported. Some are presented in Table 2, together with their practical applications.

Adsorption Chromatography

Silica gel is the most frequently used solid-phase in adsorption chromatography. The weakly acidic properties of its surface may be the reason for the chemisorption of alkaloids, especially when neutral nonpolar solvents are used.

Tailing of spots may occur and the danger in using a neutral mobile phase is the formation of double spots, resulting from partial deprotonation of molecules if alkaloids are applied as salts. This is why

Figure 2 Dependence of the degree of dissociation of an alkaloid (B) on pH of buffer in mixed solvent ($\Delta pK_{a(B)} < 0$ and $\Delta pH_m > 0$). 1, solution in water; 2, solution in mixed solvent $pK_{a(B)}^* = pK_a$ in 50% (w/w) methanol (after Popl M, Fährnich J and Tatar V (1990) *Chromatographic Analysis of Alkaloids. Chromatographic Science*. New York and Basel: Marcel Dekker, Inc.).

Table 1 Values of pK_a for the dissociation of alkaloids in water

<i>Alkaloid</i>	pK_a	<i>Alkaloid</i>	pK_a
Aconitine	8.35	Methylecgonine	9.16
Arecaidine	9.07	Morphine	8.21
Arecoline	7.41	Narceine	3.30
Atropine	9.85	α -Narcotine	6.37
Benzoylecgonine	11.80	Nicotine	8.02
Berberine	11.73		($pK_{a2} = 3.12$)
Brucine	8.16	Nicotyrine	4.76
	($pK_{a2} = 2.50$)	Papaverine	6.40
Caffeine	1.00	<i>d,l</i> -Pelletierine	9.40
Cinchonidine	8.40	Pilocarpine	6.87
	($pK_{a2} = 4.17$)	Piperine	1.98
Cinchonine	8.35	Protopine	5.99
	($pK_{a2} = 4.28$)	Quinidine	8.77
Cocaine	8.39		($pK_{a2} = 4.20$)
Codeine	8.21	Quinine	8.34
Colchicine	1.85		($pK_{a2} = 4.30$)
α -Coniine	10.90	Retronecine	8.88
Cytisine	8.12	1-Scopolamine	7.55
	($pK_{a2} = 1.20$)	Solanine	7.54
Emetine	8.43	Sparteine	11.96
	($pK_{a2} = 7.56$)		($pK_{a2} = 4.80$)
Ergometrine	6.73	Strychnine	8.26
Harmine	7.61		($pK_{a2} = 2.50$)
Heliotridine	10.55	Thebaine	8.15
Heroine	7.60	Theobromine	1.00
1-Hyoscyamine	9.65	Theophylline	1.00
		Tropacocaine	9.88
Isopilocarpine	7.18	Tropine	10.33
		Yohimbine	7.45
			($pK_{a2} = 3.00$)

silica gel is most often used in combination with basic mobile phases or the gel is impregnated with basic buffers or basic compounds (KOH, NaOH, NaHCO_3). Colchicine is the exception to these rules and, because of its neutral character, can be analysed in neutral solvent systems in combination with silica gel plates.

There are fewer applications using alumina. Basic alumina is most often used. The weakly basic character of the surface allows the use of neutral solvent systems as mobile phases. Depending on the nature of the alkaloids examined, neutral or acidic alumina may sometimes be more suitable.

As presented in detail in Table 2, solvent systems used in adsorption chromatography are either binary or ternary mixtures of chloroform, benzene, ethyl acetate and others. Alkalification of the mobile phase is achieved by the addition of ammonia, diethylamine, triethylamine or triethanolamine. Very interesting methods for choosing a suitable solvent were proposed in the late 1960s, and were based on the weighted average values of dielectric constants, and by the introduction of homogenous azeotropic

mixtures (methanol-chloroform-methyl acetate, methanol-acetone-chloroform, methanol-benzene). When choosing the proper solvent strength, especially in complex eluent mixtures used for the analysis of alkaloids, the x_e , x_d , x_n parameters developed by Snyder are useful. They refer to the possibility of a solvent acting as a proton acceptor, proton donor or the one exhibiting strong dipole interaction. All possible compositions of quaternary, ternary and binary solvent mixtures have been described by the Prisma model. It may be applied either in normal or reversed-phase systems with the aim of optimizing the conditions of separation.

Pseudo-reversed-phase Chromatography

Chromatographic systems composed of silica gel and buffered aqueous organic mobile phases have been successfully used in recent years to isolate and separate alkaloids. The retention mechanism occurring here, described as pseudo-reversed phase, is fairly complex. An important role is played by the hydrophobic

Table 2 Examples of the most popular chromatographic systems for TLC of the main alkaloid groups

Compounds separated	Applications	Adsorbent	Solvent system
<i>Phenylethylamine derivatives</i>			
Ephedrine and its derivatives	Qualitative identification of ephedrine	Silica gel	Butanol–acetic acid–water (6 : 3 : 1)
		Silanized silica gel	1 mol L ⁻¹ acetic acid–3% potassium chloride
	Determination of ephedrine in Herba Ephedrae	Silanized silica gel impregnated with anionic and cationic detergents	1 mol L ⁻¹ acetic acid–methanol (80 : 20)
		Silica gel	Isopropyl ether–acetone–tetrahydrofuran (15 : 3 : 2)
Colchicine and related compounds	Determination of ephedrine in bulk drugs	Silica gel	<i>n</i> -Butanol–water–formic acid (7 : 2 : 1)
	Determination of colchicine in bulk drugs, dragees (BP)	Silica gel	Chloroform–acetone–ammonium hydroxide (5 : 4 : 0.2 or 25 : 20 : 0.4)
	Analysis of colchicine in tablets and plant material: <i>Colchicum autumnale</i> seeds, <i>Iphigenia indica</i>	Aluminium oxide	Chloroform–methanol (80 : 0.5)
	Separation of colchicine and 3-demethylocolchicine, demecolcine in Turkish <i>Colchicum</i> and <i>Merendera</i> species	Silica gel	Benzene–ethyl acetate–butylamine (5 : 4 : 1 or 7 : 2 : 1)
<i>Imidazole alkaloids</i>			
Pilocarpine	Qualitative identification of pilocarpine	Silica gel	Chloroform–acetone–diethylamine (5 : 4 : 1)
	Determination of pilocarpine in ocular system	Aluminium oxide	Chloroform–acetone–water (5 : 4 : 1)
		Silica gel	Chloroform
	Determination of pilocarpine nitrate in bulk drugs (EP)	Silica gel	Methanol–1% potassium dihydrogen phosphate (pH 6 : 9 : 1)
	Separation of pilocarpine, isopilocarpine, pilocarpic acid and isopilocarpic acid in eye drops	Silica gel	Chloroform–methanol–ammonium hydroxide (85 : 14 : 1)
<i>Indole alkaloids</i>			
Strychnos alkaloids	Determination of strychnine in biological specimens	Silica gel	Ethanol–chloroform–28% ammonium hydroxide (53 : 30 : 17)
	TLC analysis of strychnine and brucine in plant extract from <i>Strychnos nux vomica</i>	Silica gel	Dichloromethane–methanol–water–formic acid–diethanolamine (72.3 : 25 : 2.5 : 0.1 : 0.1)
	Separation of strychnine and brucine	Aluminium oxide	Methanol–4 mol L ⁻¹ ammonium hydroxide (9 : 1)
Yohimbine type Rauwolfia alkaloids and related bases	Determination of reserpine in <i>Rauwolfia serpentina</i> and <i>R. cubana</i> stem bark	Silica gel	Benzene–ethanol (9 : 1 or 8 : 2)
	Isolation of alkaloids from <i>Mitragyna speciosa</i>	Cellulose	Chloroform–methanol (19 : 1 or 9 : 1)
		RP-18	Ethyl acetate–cyclohexane–diethylamine (210 : 90 : 1)
	TLC analysis of extract from <i>Uncaria</i>	Silica gel	Butanol–acetic acid–water (60 : 15 : 25)
	Determination of serpentine and ajmalicine in <i>Catharanthus roseus</i>		Methanol–water (4 : 2)
		Silica gel	Chloroform–acetone (5 : 4)
	TLC analysis of ajmaline stereoisomers, vincine, vincamine	Silica gel	Ethyl acetate–isopropanol–ammonium hydroxide (100 : 2 : 1)

Table 2 *Continued*

<i>Compounds separated</i>	<i>Applications</i>	<i>Adsorbent</i>	<i>Solvent system</i>
Ergot alkaloids	Determination of ergotamine tartrate in bulk drugs and dihydroergotamine mesylate (USPXXI, EP, BP)	Silica gel	Dimethylformamide-ether-chloroform-ethanol (15 : 70 : 10 : 5) Chloroform-ethanol (9 : 1)
	Qualitative identification of hallucinogen ergot alkaloids from <i>Ipomoea Tricolor Cav</i>	Silica gel	Ethanol-tetrahydrofuran-ethyl acetate (1 : 1 : 8) Water-ethanol-ether (5 : 35 : 60) Acetonitrile-ethanol-toluene (85 : 10 : 5) Water-ethanol-ether (1 : 7 : 12) Acetonitrile-ethanol-toulene (17 : 2 : 1)
	Quantitative analysis of ergot alkaloids: lysergol, ergometrine, agroclavine, ergotamine, ergocristine, ergotamine, ergocristinine	Silica gel (circular U-RPC)	
	Qualitative identification of ergot alkaloids	Silica gel	Stepwise gradient elution: 1 Chloroform-diethylamine (12 stages, 7 steps) 2 Chloroform-acetone-diethylamine (11 stages, 5 steps)
<i>Pyridine and piperidine alkaloids</i>			
Tobacco alkaloids	Rapid TLC identification of cytisine and nicotine	Silica gel	Dichloromethane-methanol-10% ammonium hydroxide (83 : 15 : 2)
	Determination of nicotine, nor nicotine, anabasine, nicotyrine, 2,2-dipiridyl	Silica gel (OPLC)	Ethyl acetate-methanol-water (12 : 35 : 3)
Tropane alkaloids	Quantitative determination of atropine in Chinese medicine	Silica gel	Chloroform-acetone-methanol-ammonium hydroxide (70 : 10 : 15 : 1)
	Determination of atropine in pharmaceutical preparations: bulk drugs and injections (USPXXI)	Silica gel	Chloroform-diethylamine (9 : 1)
	Qualitative identification of atropine, scopolamine, tubocurarine in African arrow poison	Silica gel	Chloroform-cyclohexane-diethylamine (3 : 6 : 1)
	TLC analysis of <i>Belladonna</i> tinctura (atropine, scopolamine)	Silica gel with micro-crystalline cellulose (5 : 2)	Chloroform-acetone-methanol-ammonium hydroxide (73 : 10 : 15 : 2)
	Analysis of <i>Hyoscyamus</i> extract	Silica gel	Methanol-ammonium hydroxide (98 : 2) Chloroform-butylamine (9 : 1) Ethyl acetate-formic acid-ammonium hydroxide (10% : 83 : 15 : 2) Water-methanol-sodium acetate buffer (0.2 mol L ⁻¹ aqueous: 28 : 12 : 60 : 1)
Pseudotropine alkaloids	Determination of cocaine and local anaesthetics	Silica gel	Two-dimensional: 1 Cyclohexane-benzene-diethylamine (75 : 15 : 10) 2 Chloroform-methanol (8 : 1) Chloroform-ethanol (1 : 1) Butanol-ethanol (95 : 1)
	Identification of alkaloids in <i>Erythroxylum hypericifolium</i> leaves	Aluminium oxide	
<i>Quinoline alkaloids</i>			
Cinchona alkaloids	Quantitative analysis of 17 cinchona alkaloids	Silica gel	Chloroform-acetone-methanol-25% ammonium hydroxide (60 : 20 : 20 : 1)
	TLC analysis of cinchona alkaloids as pure substances	Silica gel	Chloroform-diethylamine (9 : 1) Chloroform-methanol-ammonium hydroxide (25% : 85 : 14 : 1) Kerosene-acetone-diethylamine (23 : 9 : 9)

Table 2 Continued

Compounds separated	Applications	Adsorbent	Solvent system
			Toluene–diethyl ether–diethylamine (20 : 12 : 5)
	Determination of quinidine and dihydroquinidine in serum	Silica gel	Ethyl acetate–ethanol– <i>n</i> -butanol–ammonium hydroxide (56 : 28 : 4 : 0.5)
	Preparative TLC quinoline alkaloids from <i>Orixa japonica</i> stems	RP-18 Silica gel	Methanol–water (2 : 1) Benzene–ethyl acetate (4 : 1)
	Determination of quinine hydrochloride, quinidine sulfate in bulk drugs (EP, BP)	Silica gel	Diethylamine–ether–toluene (10 : 24 : 40)
	Determination of cinchonine in bulk drugs	Silica gel sprayed with 0.1 mol L ⁻¹ methanolic potassium hydroxide	Ammonium hydroxide–methanol (1.5 : 100)
<i>Isoquinoline alkaloids</i>			
Protoberberine and protopine alkaloids	Determination of berberine in biological matrix	Silica gel	Ethyl acetate–methyl acetate–methanol–water (27 : 23 : 6 : 5)
	Separation of berberine in presence of quaternary alkaloids in plant extracts	Silica gel (OPLC)	Ethyl acetate–tetrahydrofuran–acetic acid (6 : 2 : 2)
	Quantitative analysis and qualitative identification of protoberberine alkaloids	Silica gel	Two-step development in twin trough chamber: 1 Ethyl acetate–methanol–ammonium hydroxide (10 : 10 : 1) 2 Benzene–ethyl acetate–isopropanol–methanol–water (20 : 10 : 5 : 5 : 1) Second trough containing 5 mL conc. NH ₃
	Quantitative analysis of berberine in capsule	Silica gel	Ethyl acetate–acetone–formic acid–water (20 : 17 : 4 : 2)
	TLC analysis of protopine and allocryptopine from Turkish <i>Papaver curviscapum</i>	Silica gel	Benzene–ethanol–ammonium hydroxide (8 : 2 : 0.03) Benzene–acetone–methanol (7 : 2 : 1) Toluene–acetone–methanol–ammonium hydroxide (45 : 45 : 7 : 3)
	Determination of berberine in bulk drugs	Silica gel sprayed with 0.1 mol L ⁻¹ methanolic potassium hydroxide	Ammonium hydroxide–methanol (1.5 : 100)
	Determination of sanguinarine, chelidonine, protopine, allocryptopine in <i>Chelidonium majus</i>	Silica gel	Toluene–methanol–diethylamine (60 : 5 : 2) saturated with formamide
Morphine alkaloids	Analysis of morphine alkaloids in opium	Silica gel	Benzene–ethanol (17 : 1 or 9 : 1) Benzene–dioxane–ethanol–ammonium hydroxide (50 : 40 : 5 : 5) Toluene–acetone–ethanol (96%)–ammonium hydroxide (25%) (45 : 45 : 7 : 3) Hexane–chloroform–diethylamine (50 : 30 : 7) Ethyl acetate–methanol–ammonium hydroxide (85 : 10 : 5 or 75 : 20 : 5) Chloroform–triethanolamine (95 : 5) Chloroform–methanol–water (7 : 5 : 1) Butanol–ammonium hydroxide–water–methanol (20 : 1 : 4 : 2)
	Determination of morphine and semisynthetic derivatives	Silica gel	

Table 2 Continued

Compounds separated	Applications	Adsorbent	Solvent system
Isoquinoline bases	Determination of Dabsyl derivatives of morphine in urine	Silica gel	Chloroform-ethanol-triethanolamine (30 : 2 : 0.05)
	Determination of papaverine, codeine, eupaverine	RP-18 (IP-TLC)	Water-acetone (20 : 80, 100 : 0) with 0.1 mol L ⁻¹ of ion reagent-sodium alkylsulfonate
	Determination of emetine and tubocurarine	Silica gel	Ethyl acetate-isopropanol-ammonium hydroxide (25% : 9 : 7 : 2)
	TLC analysis of emetine hydrochloride in bulk drugs (USPXXI, BP)	Silica gel	Chloroform-diethylamine (9 : 1)
	TLC analysis of codeine in bulk drugs (EP)	Silica gel	Ammonium hydroxide-cyclohexane-ethanol (6 : 30 : 72)
	TLC analysis of papaverine hydrochloride in bulk drugs (EP)	Silica gel	Diethylamine-ethyl acetate-toluene (1 : 2 : 7)
	Determination of codeine, chlorpheniramine, phenylephrine, paracetamol (acetaminophen) in syrup and tablets	Silica gel	Butanol-methanol-toluene-water-acetic acid (3 : 4 : 1 : 2 : 0.1)
Benzylisoquinoline alkaloids	Determination of alkaloids in <i>Anisocycla cymosa</i> roots and plant extract	Silica gel	Chloroform-methanol-diethylamine-ammonium hydroxide (8 : 2 : 2 : 0.5) Benzene-acetone-ammonium hydroxide (15 : 15 : 1)
	Determination of bisbenzylisoquinoline alkaloids in <i>A. jollyana</i> leaves	Silica gel	Chloroform-toluene-methanol-acetone-ethyl acetate-ammonium hydroxide (270 : 30 : 80 : 30 : 3)
Aporphine alkaloids	Analysis in plant material	Aluminium oxide	Toluene-chloroform-methanol-ammonium hydroxide (100 : 150 : 40 : 3)
		Silica gel	Cyclohexane-ethyl acetate (3 : 2) Cyclohexane-acetone (9 : 1) Petrol ether-acetone (7 : 3) Chloroform-methanol (9 : 1)
Various isoquinoline alkaloids	Determination of cocaine, heroin and local anaesthetics in street drugs	Silica gel	Benzene-chloroform-triethanolamine (9 : 9 : 4) Ethyl acetate-isopropanol-28% ammonium hydroxide (40 : 30 : 3)
	Analysis of major drugs of abuse in urine	Silica gel	Ethyl acetate-cyclohexane-methanol-ammonium hydroxide (conc.)-water (70 : 15 : 8 : 2 : 0.5) Ethyl acetate-cyclohexane (50 : 60)
<i>Diterpene and steroidal alkaloids</i>			
Diterpene	Determination of aconitine nitrate in bulk drugs	Silica gel spray 0.1 mol L ⁻¹ potassium hydroxide methanol	Ammonium hydroxide-methanol (1.5 : 100)
	Determination of aconitine, 3-deoxyaconitine, mesaconitine in <i>Wutou</i> and <i>Aconitum</i>	Silica gel	Cyclohexane-ethyl acetate-ethylenediamine (8 : 1 : 1)
	Isolation of norditerpenoid alkaloids from extract of roots of <i>Delphinium tatsienense</i> TLC of 8 diterpenoid alkaloids from <i>Aconitum septentrionale</i>	Aluminium oxide (neutral)	Gradient elution: hexane, hexane-diethyl ether (25 : 75), diethyl ether, diethyl ether-methanol
		Silica gel (centrifugal TLC)	Diethyl ether-75% methanol-0.3% diethylamine
		Silica gel (preparative TLC)	Diethyl ether-5% methanol
		Silica gel	Hexane-chloroform (6 : 4)
		Aluminium oxide (centrifugal TLC)	Chloroform-methanol (8 : 2 or 97 : 3) Gradient of hexane, ether and methanol

	Determination of caffeine, theophylline and 15 drugs in Chinese herbal preparations	Silica gel	Dichloromethane-methanol-water (183 : 27 : 5) Ethyl acetate-toluene-dimethylformamide-formic acid (75 : 70 : 4 : 2) Dichloromethane-methanol (183 : 27) Ammonium hydroxide-acetone-chloroform-butanol (1 : 3 : 3 : 4)
	Determination of caffeine and theobromine in bulk drugs (EP)	Silica gel	
	Determination of theophylline in capsules (USPXXI) in tablets with ephedrine hydrochloride and phenobarbital (USPXXI, EP)	Cellulose Silica gel	Methanol-water Chloroform-acetone-methanol-ammonium hydroxide (50 : 10 : 10 : 1)
Quinolizidine	Qualitative identification	Silica gel Aluminium oxide	Chloroform-cyclohexane-butylamine (5 : 4 : 1) 1.5% Methanol in chloroform

BP, British Pharmacopoeia; EP, European Pharmacopoeia, USPXXI, The United States Pharmacopoeia, Twenty-first Revision.

interactions of siloxane groups with the non-polar fragments of the separated alkaloids, as well as by ion exchange interactions. In the retention of alkaloids a dominant role is played by the ion exchange mechanism which is due to the weak cation exchange prop-

erties of silica gel at pH = 2–8 and the fact that aromatic amines chromatographed in an aqueous mobile phase are weakly protonized at pH = pK_a – 1. The selectivity of such systems depends then, primarily, on the pH of the mobile phase but

also on the kind of organic modifier, which is usually methanol or acetonitrile.

Reversed-phase Chromatography

Nonpolar adsorbents have rarely been applied in TLC of alkaloids, perhaps because of the low efficiency of such systems, which is caused by the interaction of alkaloid molecules with silanol groups present on the adsorbent surface in addition to the hydrocarbon chains. In reversed-phase chromatography on silanized silica gel, alkaloids as easily ionized compounds require specific conditions of analysis such as suppression of dissociation, ion suppression or the application of specific ion pair reagents.

The suppression of dissociation is achieved with a mobile phase of a suitable pH ($\text{pH} \geq \text{pK}_a$) for the specific solvent, in accordance with the curve shown in Figure 2.

Reversed-phase conditions may also be obtained by impregnating silica gel with paraffin or silicone oil. Additionally, chemically bonded reversed phases with polar groups (cyano- and amino-layers) have been employed. Their properties depend on the kind of compounds to be separated and on the composition of the mobile phase.

Ion Pair Chromatography

The use of ion pair chromatography (IP-TLC) of alkaloids may be carried out on normal and reversed phases. This technique has been applied to analyse basic drugs, including alkaloids, on silica gel using normal-phase systems. The best results are obtained by applying chloride and bromide as counterions of at least 0.1 mol L^{-1} concentration in the spreading slurry or in the solvent.

Reversed-phase IP-TLC is far more widely used. The counterion reagents which may be present in the mobile phase and serve for impregnation in the nonpolar stationary phase may be di-(2-ethylhexyl) orthophosphoric acid (HDEHP), camphoric and camphorosulfonic acids, sodium dodecylsulfate and simple hydrophilic anionic reagents such as perchloric acid, oxalic acid and trichloroacetic acid. The acidic environment of the mobile phase ensures ionization of the acidic counterions and enables the creation of an ion pair with the alkaloids protonized under these conditions. The behaviour of some isoquinoline bases using RP-18 plates and alkylsulfonates as counterions has also been investigated.

Although retention and separation selectivity in IP-TLC depend on many factors, optimization of such chromatographic systems is basically concerned with pH changes, concentration and the chain length

of the counterion or the concentration of organic modifier in the mobile phase.

Partition Chromatography

In the past, partition chromatography conducted on paper was a perfect model for establishing optimum extraction systems for alkaloid isolation. In paper chromatography, the system allowing partition conditions is mainly composed of cellulose with an aqueous solvent or an aqueous buffer solution of pH 3–7, depending on the nature of the alkaloids. Silica gel combined with an aqueous phase or a water-saturated organic solvent also allows for the domination of the partition mechanism, thanks to deactivation of the surface silanol groups. The aqueous phases in such systems are often alkalized with aqueous ammonium hydroxide or acidified with hydrochloric acid.

Partition conditions, similar to paper chromatography, may be obtained by impregnating cellulose or silica gel with a solution of formamide in ethanol and using mobile phases immiscible with the stationary phase, such as chloroform, benzene, cyclohexane or their mixtures.

Ion Exchange Chromatography

Ion exchange techniques are applied for both crude fractionation and separation and determination of alkaloids.

The typical ion exchange sorbents used for TLC of alkaloids have been as follows: anion exchangers AG 1-X4 and Cellex D, and cation exchangers with cellulose (alginic acid and sodium carboxymethylcellulose), paraffin (Rexyn 102) and polystyrene (Dowex 50-X4) matrices.

While choosing the best eluent for ion exchange chromatography, pH values should be carefully considered. They are closely correlated with the number of charges in the alkaloid molecules and at the same time decide the retention values. The trends for most alkaloids fit the type of curves shown in Figure 3.

One of the popular adsorbents which may function as an ion exchanger is aluminium oxide (Al_2O_3) with an aqueous mobile phase. Depending on the kind of aluminium oxide used, a cation- or anion-exchanging mechanism may occur. Thus, in aqueous alcoholic solution basic alumina functions as a cation exchanger (I), but acidic alumina acts as an anion exchanger (II). With neutral alumina, both types of reactions may take place depending on the conditions used:

Figure 3 R_M versus pH curves for some alkaloids on alginic acid thin layers (after Lepri L, Desideri PG and Lepori M (1976) Chromatographic Behaviour of Alkaloids of Thin Layer of Cation Exchangers. Journal of Chromatography 123, 175. Amsterdam: Elsevier).

Adsorbents Impregnated with Metal Salts

The use of silica gel and aluminium oxide impregnated with metal salts (cadmium and zinc nitrate) for the separation of some alkaloids has been studied.

For steroid alkaloids, the impregnation of the stationary phase with silver salts – so-called argentation TLC – has been applied. This technique is based on the formation of π -complexes with the separated compounds during the chromatographic process.

Detection of Alkaloids

Only a few alkaloids are directly visible on the chromatogram as coloured spots and visualization methods have to be applied to detect them. In order to detect the compounds under UV light, fluorescing indicators are added to the adsorbent.

Alkaloids become visible in short wavelength UV light ($\lambda = 254$ nm), where they appear as dark zones on a fluorescent background. This is considered to be a nonselective method of detection because, on the layer containing a fluorescent indicator, the emission is quenched in regions where all aromatic organic

compounds absorb the UV light with which the plates are irradiated.

Some alkaloids, such as indoles, quinolines, isoquinolines and purines, cause pronounced quenching of fluorescence, but some (e.g. tropine alkaloids) only weakly quench UV light. Sometimes compounds can be detected under a UV lamp due to their own luminescence. Excitation is usually performed using long wavelength radiation of $\lambda = 365$ nm. Alkaloids absorb radiation and then usually emit it in the visible region of the spectrum, where they appear as bright-coloured luminous zones of blue, blue-green or violet, for example, *Rauwolfia radix*, *Chinae cortex*, *Ipecacuanhae radix*, *Boldo folium*, and of yellow, e.g. *colchicine*, *sanguinarinae*, *berberine*.

Other methods of physical detection make the most of the chemical properties of alkaloids. As basic compounds, these properties can be detected using pH indicators applied to the chromatogram by dipping it or spraying it with 0.01–1% indicator solutions.

Bromocresol Green with pH transition from 3.8 to 5.4 is applied for many alkaloids; Bromocresol Purple (pH = 5.2–6.8) is predominantly applied for ephedrine.

Another nonselective detection method for alkaloids as lipophilic substances is the treatment of a chromatogram with iodine vapour or dipping into or spraying with 0.5–1% iodine solutions. Molecular iodine is enriched in the chromatogram zones and colours them brown. Emetine and cephaeline, the two major alkaloids of *ipecacuanha*, begin to glow after treatment with iodine vapour. In this case, the molecular iodine which acts as a quencher must be removed by heating, before the yellow (emetine) and blue (cephaeline) fluorescent zones become visible.

Although the methods described are usually fairly sensitive and allow a detection limit of less than 1 μ g, sometimes they are insufficient. That is why they have to be supplemented by specific reactions with a number of detection reagents (Table 3).

The most popular reagents which react with tertiary and quaternary nitrogen atoms present in alkaloid molecules are Dragendorff's reagent and potassium iodoplatinate. Alkaloids containing primary and secondary amino groups treated with dimethyl sulfate give quaternary nitrogen atoms, permitting effective detection with these reagents too.

Dragendorff's and iodoplatinate reagents exist in various modifications. The replacement of water in these reagents by acetic acid or ethyl acetate, diethyl ether–methanol or hydrochloric acid increases the sensitivity of the reaction and significantly improves the sharpness of spots. Spraying 10% sodium nitrate solution after the use of Dragendorff's reagent causes

Table 3 Selection of detection reagents for postchromatographic derivatization of alkaloids

Reagent	Substances detected	Reaction	Method	Result
Ammonia vapour	Alkaloids, e.g. morphine, heroin, 6-mono-acetylmorphine	Morphine and heroin form fluorescent oxidation products	Heat the chromatogram in the drying cupboard to 110–120°C for 25 min and place it for 15 min in a twin-trough chamber, whose second trough contains 10 mL of 25% ammonia solution. Then immerse for 2 s in a solution of liquid paraffin– <i>n</i> -hexane (1 : 2)	Morphine, 6-monoacetylmorphine and heroin appear as blue fluorescent zones on a dark background under UV light ($\lambda = 365$ nm). In each case the detection limits are 2 ng of substance per chromatographic zone. The fluorimetric determination is carried out in UV light $\lambda_{\text{exc}} = 313$ nm, $\lambda_{\text{fl}} = 390$ nm
Formaldehyde reagent (1,2-naphthoquinone-4-sulfonic acid)–perchloric acid	Alkaloids, e.g. codeine, morphine, heroin, 6-mono-acetylmorphine	The reaction mechanism has not been elucidated. It is possible that formaldehyde reacts by oxidation, as in Marquis reaction	Dry the chromatogram in a stream of warm air for 5 min, immerse in the reagent solution for 4 s and heat to 70°C for <i>c.</i> 10 min	Morphine alkaloids yield blue chromatogram zones on a pale blue background. The detection limits are 10–20 ng of substance per chromatogram zone. The absorption photometric analysis can be performed at reflectance $\lambda = 610$ nm
2-Methoxy-2,4-diphenyl-3(2H)-furanone (MDPF)	Alkaloids from <i>Colchicum autumnale</i> (Colchicine)	MDPF reacts directly with primary amines to form fluorescent products	Free the chromatogram from mobile phase in a stream of warm air (45 min), immerse in the reagent solution for 4 s and then heat to 110°C for 20 min	Colchicine appears as a yellow fluorescent zone on a dark background in UV light (365 nm). The detection limit is 10 ng per chromatogram zone. The fluorimetric analysis is carried out with excitation at $\lambda_{\text{exc}} = 313$ nm, and evaluation at $\lambda_{\text{fl}} > 390$ nm
2,4-Dinitrophenyl-hydrazine	Alkaloids	Reagent reacts with carbonyl groups with the elimination of water to yield hydrazone and with aldoses or ketoses to yield coloured osazones	Immerse the chromatogram in the dipping solution for 2 s or spray and then dry in a stream of warm air (10–20 min at 110°C)	Substances yield yellow to orange-yellow chromatogram zones on an almost colourless background
2,6-Dichloro-quinone-4-chloroimide	Isoquinoline alkaloids	Reagent reacts with phenols or anilines which are not substituted in the <i>p</i> -position	Dry the chromatogram for 5 min in a stream of warm air, immerse in the dipping solution for 5 s and then heat to 110°C for 2 min	Cephealine produces a blue colour immediately on immersion, while emetine only does so on heating. On storage this colour slowly changes to brown (background light brown). The detection limits are <i>c.</i> 10 ng per chromatogram zone. The absorption photometric analysis was made at $\lambda = 550$ nm
α -Phthalaldehyde (OPT, OPA)	Ergot alkaloids	In the presence of 2-mercaptoethanol, α -phthalaldehyde reacts with primary amines to yield fluorescent isoindole derivatives	Immerse the dried chromatogram for 1 s in the reagent solution and then heat to 40–50°C in the dry cupboard for 10 min	Substance zones are produced that mainly yield blue (or yellow) fluorescence under long wavelength light ($\lambda = 365$ nm)
Phosphomolybdic acid	Morphine	Morphine can be oxidized with phosphomolybdic acid, whereby a portion of the Mo(VI) is reduced to Mo(IV) which forms blue-grey oxides with the remaining Mo(VI)	Dry the chromatogram in a stream of warm air and immerse for 2–3 s in the reagent solution, or spray the layer with it	Blue zones appear on a yellow background immediately or after a few minutes

Table 3 *Continued*

<i>Reagent</i>	<i>Substances detected</i>	<i>Reaction</i>	<i>Method</i>	<i>Result</i>
Trichloroacetic acid	Alkaloids from, e.g. <i>Veratrum colchicum</i>	The reaction mechanism has not yet been elucidated	Dry the chromatogram in a stream of cold air and immerse for 1 s in the reagent solution or spray with it and then heat at 120°C for 10 min	Light blue fluorescent zones appear mainly under long wavelength UV light ($\lambda = 365$ nm). The fluorescence can be stabilized and intensified by dipping the plate into a solution of liquid paraffin- <i>n</i> -hexane (1 : 2)
Sulfuric acid	Alkaloids	The reaction mechanism has not yet been elucidated	Dry the chromatogram in a stream of warm air for 10 min, immerse in the dipping solution for 1–2 s or spray with the spray solution, dry in a stream of warm air and then heat to 95–140°C for 1–20 min	Under long wavelength UV light ($\lambda = 365$ nm) characteristic substance-specific yellow, green, red and blue fluorescent chromatogram zones usually appear, and are often recognizable in visible light
7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-chloride reagent)	Alkaloids	NBD reacts with nucleophilic compounds to yield the corresponding 7-substituted 4-nitrobenzofurazan derivatives	Dry the chromatograms. Immerse in dipping solution of sodium acetate in methanol–water for 1 s. Dry in a stream of warm air and dip after cooling in NBD-chloride reagent in ethanol and then heat to 100°C for 2–3 min. Alternatively the chromatogram can be sprayed with the appropriate spray solutions	Under UV light ($\lambda = 365$ nm) the chromatogram zones fluoresce greenish-yellow, olive brown or violet. The plate background also fluoresces, but appreciably less. The detection limits are 100–800 ng substance per chromatogram zone
<i>tert</i> -Butyl hypochlorite	Alkaloids	The reaction mechanism has not yet been elucidated	Dry the chromatogram, immerse in dipping solution of reagent in carbon tetrachloride or cyclohexane for 1 s (or spray or expose to its vapours) then immerse in dipping solution of chloroform, paraffin oil and triethanolamine (6 : 1 : 1) for 1 s and dry in hot air	The analysed compounds appear in long wavelength UV light (365 nm), yellow to violet fluorescent zones, on a dark background. The detection limit for morphine is 10 ng and for papaverine 1 ng per chromatogram zone
Formaldehyde-sulfuric acid (Marquis reagent)	Alkaloids, e.g. morphine, codeine, heroin, 6-monoacetyl-morphine	Morphine reacts with formaldehyde in acidic solution to yield a cyclic ketoalcohol, which is transformed into the coloured oxonium or carbenium ion in acidic conditions	Dry the chromatogram in a stream of warm air for 5 min, immerse in the dipping solution for 6 s and heat to 110°C for 20 min	Morphine alkaloids yield reddish chromatogram zones (codeine yielded blue on a pale pink background). If a quantitative fluorimetric analysis is to follow, the chromatogram is exposed to ammonia vapour for 20 min and immersed for 2 s in 20% dioctyl sulfosuccinate in chloroform. After drying, morphine alkaloids appear as pink to red fluorescent zones on a blue fluorescent background under UV light ($\lambda = 365$ nm). The fluorimetric analysis is carried out at $\lambda_{\text{exc}} = 313$ nm, $\lambda_{\text{fl}} = 560$ nm

Table 3 *Continued*

<i>Reagent</i>	<i>Substances detected</i>	<i>Reaction</i>	<i>Method</i>	<i>Result</i>
Iron (III) chloride-perchloric acid (FCPA reagent)	Indole alkaloids, e.g. from <i>Rauwolfia</i> , <i>Tabernaemontana</i> , <i>Mitragyna</i> , <i>Strychnos</i> , <i>Synclisia</i> , <i>Cinchona</i>	The reaction mechanism has not yet been elucidated	Free the chromatogram from mobile phase in a stream of warm air (45 min), immerse in the dipping solution for 4 s. Dry and heat to 110°C for 20 min	Variously coloured chromatogram zones are produced on a colourless background. For instance, strychnine appears as a red and brucine as a yellow chromatogram zone on a colourless background. The detection limit for both is 10 ng per chromatogram zone. The light absorption in reflectance was measured at $\lambda = 450$ nm
Hydrochloric acid vapour	Alkaloids, e.g. papaverubines	The reaction mechanism has not yet been elucidated	Free the chromatogram from mobile phase (first in a stream of cold air for a few minutes, than at 100°C for 5 min), place in the free trough of the prepared twin-trough chamber for 5 min and then evaluate	Alkaloids are visible after irradiation with unfiltered UV light from a mercury lamp

Figure 4 (See Colour Plate 54). The chromatograms of the separated alkaloids developed on silica gel or alumina in solvent systems 1–4, detected with different reagents. Solvent systems: 1, toluene–ethyl acetate–diethylamine (70 : 20 : 10); 2, chloroform–diethylamine (90 : 10); 3, toluene–chloroform–ethanol (28.5 : 57 : 14.5); 4, 1-propanol–water–formic acid (90 : 9 : 1). For identification of compounds, reagents used and obtained results, see Table 4. (Reproduced with permission from Wagner H and Bladt S (1996) *Plant Drug Analysis. Thin-layer Chromatography Atlas*. Berlin: Springer.)

Table 4 Symbols used in Figure 4

Symbol	Detection	Solvent system	Reference compounds	Result
A	Marquis reagent → vis	1	Morphine (1), codeine (2), papaverine (3), noscapine (4), opium extract (5)	Morphine and codeine are immediately stained violet; papaverine: weak violet; noscapine: weak yellow brown
B	Natural products, polyethylene glycol reagent (NP/PEG) → UV 365 nm	1		Morphine, papaverine, noscapine give a blue fluorescence in UV 365 nm; codeine does not fluoresce
C	Sulfuric acid reagent → UV 365 nm	1	Serpentine (1), quinine (2), cinchonine (3), quinidine (4), cinchonidine (5), cephaeline (6), emetine (7), yohimbine (8), noscapine (9), hydrastine (10), berberine (11), sanguinarine (12)	The fluorescence of quinine and quinidine is a radial blue; cinchonine and cinchonidine: deep violet, berberine and sanguinarine: bright yellow
D	Dragendorff reagent → vis		Strychnine (1), yohimbine (2), physostigmine (3), nicotine (4), veratrine (5), emetine (6), papaverine (7), lobeline (8), aconitine (9), narcotine (10)	Alkaloids give orange-brown, stable colours
E	Dragendorff reagent followed by sodium nitrite → vis	1		The zones become dark brown
F	Iodine/CHCl ₃ reagent → UV 365 nm	1	<i>Cephaelis accuminata</i> (1), cephaeline: $R_f \sim 0.2$; emetine: $R_f \sim 0.4$ (2).	Cephaeline fluoresces bright blue and emetine: yellow-white
G	→ vis	1	<i>Cephaelis ipecacuanha</i> (3)	Cephaeline gives red and emetine weak yellow zones
H	10% H ₂ SO ₄ followed by iodoplatinate reagent → vis	2	China alkaloid mixture (1) <i>Cinchona succirubra</i> (2)	The violet-brown zone of quinine is followed by the grey-violet zone of cinchonidine, a weak red-violet zone of quinidine and brown-red cinchonine (1) In <i>Cinchona succirubra</i> extract additionally three red-violet zones appear in the R_f range 0.4–0.6 (2)
I	van URK reagent → vis	3	Ergocristine (1), <i>Secale cornutum</i> (2), ergotamine (3), ergometrine (4)	Secale alkaloids appear as blue zones in the R_f range of 0.05–0.4
J	UV 254 nm	1	Strychnine (1), <i>Strychni semen</i> (2), <i>Ignatii semen</i> (3), brucine (4)	Strychnine and brucine are characterized in UV 254 nm by their strong quenching zones
K	UV 365 nm	4	<i>Chelidonii herba</i> different trade samples (1–3), sanguinarine (4)	The major alkaloid coptisin at $R_f \sim 0.15$ (bright-yellow) is followed by berberine, chelerythrine, sanguinarine (broad yellow) and chelidonine (weak yellow-green) in the R_f range of 0.75–0.85

the colour of alkaloid zones to be intensified or stabilized and increases the sensitivity to 0.01–0.1 µg.

Modification, where a chromatogram is sprayed with 10% sulfuric acid after the use of Dragendorff's

reagent, also causes an increase in the sensitivity of the reaction. Potassium iodoplatinate reagent gives preliminary identification, due to the fact that different colours are obtained with different alkaloids.

Table 5 Examples of prechromatographic derivatization of alkaloids

Prechromatographic derivatization	Reagent used	Special applications
Oxidation	10% Chromic acid in glacial acetic acid Potassium dichromate Dehydration by heating the applied sample on silica layer	Strychnine and brucine
Reduction	Sodium borohydride solution	Not specified
Iodination	Iodine vapour saturated chamber (18 h)	Quinoline, isoquinoline, indole alkaloids
Nitration	Concentrated nitric acid	Brucine
Dansylation	Dansyl chloride and twice bigger volume of 8% sodium bicarbonate solution	Morphine, 6-monoacetylmorphine, morphine-6-nicotinate

TLC systems

S₁, Silica gel G, activated: chloroform–acetone–diethylamine (5 : 4 : 1).S₂, Silica gel G, activated: chloroform–diethylamine (9 : 1).S₃, Silica gel G, activated: cyclohexane–chloroform–diethylamine (5 : 4 : 1).S₄, Silica gel G, activated: cyclohexane–diethylamine (9 : 1).S₅, Silica gel G, activated: benzene–ethyl acetate–diethylamine (7 : 2 : 1).S₆, Aluminium oxide G, activated: chloroform.S₇, Aluminium oxide G, activated: cyclohexane–chloroform (3 : 7) + 0.05 diethylamine.S₈, Silica gel G, impregnated with 0.1 mol L⁻¹ sodium hydroxide, activated: methanol.(Reproduced with permission from Svendsen AB and Verpoorte R (1983) *Chromatography of Alkaloids*. Journal of Chromatography Library. Amsterdam: Elsevier.)

For particular alkaloids, specific reagents can be used; for instance, Marqui's reagent (formaldehyde–sulfuric acid) or Fröhde's reagent (sulfomolybdic acid–sulfuric acid) for morphine. König's reaction can be used to detect nicotine and related alkaloids; Wachtmeister's reagent (*bis*-diazotized benzdine–sulfuric acid) is applied for alkaloids belonging to the protoberberine and protopine group.

The Vitaly reaction is specific for the tropane alkaloids, and reaction with 4-dimethylaminobenzaldehyde for indole alkaloids. Some examples of applications of different reagents are illustrated in Figure 4 and Table 4.

The use of π -acceptor reagents producing colour spots (TCNQ: 7,7,8,8-tetracyano-quinodimethane; TNF: 2,4,7-trinitrofluorenone; TetNF: 2,4,5,7-tetranitro-9-fluorenone; DDQ: 2,3-dichloro-5,6-dicyanoquinone; DNFB: 2,4-dinitrofluorobenzene) for the detection of alkaloids has been employed.

Initial derivatization during sample preparation or *in situ* on the layer after the application of the sample is called prechromatographic derivatization and comprises oxidation, reduction, iodination, nitration and dansylation (Table 5).

Starting chromatographic separation with sample derivatization allows better-quality results to be obtained, especially as far as reproducibility and

lowering the detection limits are concerned. Morphine as a dansyl derivative is an example of fluorescence stabilization and intensity augmentation as a result of treatment of the chromatogram with a 20% solution of liquid paraffin in *n*-hexane.

A similar phenomenon is observed for codeine, morphine, monoacetylmorphine and heroin with the aid of hydrophilic liquids, such as a 20% solution of dioctyl sulfasuccinate in ethanol as a fluorescence intensifier.

Enhanced sensitivity can be achieved by impregnating the layer, by adding the reagent to the solvent or by spraying the plate after development. In addition to the reagents mentioned above, fluorescence intensifiers such as triethanolamine, glycerol and Triton X-100 are quite popular.

Identification and Quantification

The forte of TLC is qualitative analysis. It is possible to identify unknown alkaloids owing to the large amount of R_F data available from the literature and the ability to perform a chemical reaction using a wide spectrum of different reagents *in situ*. For some alkaloid drugs, a compilation of TLC data has been elaborated and stored in computer-based information systems.

Many authors make an identification based on R_F values in a number of chromatographic systems. One scheme has been described in which the analysis of a series of alkaloids by eight TLC systems, combined with observations under UV light ($\lambda = 366$ nm) and colour reactions with iodoplatinate reagent (Table 6) is used.

For precise identification, UV or infrared spectra after elution have become indispensable. Together with the melting point and optical rotation values, they are sufficient for the identification and comparison of isolated pure substances. Other spectral methods such as nuclear magnetic resonance or mass spectrometry have frequently been used to identify alkaloids.

Although quantitative determination in TLC is more difficult and requires more effort, it is becoming increasingly important nowadays. There exist two forms of quantitative analysis: direct and indirect. The first method is based on the elution of spots with a suitable solvent and determination in solution, followed by spectrophotometric, fluorometric or acid-base potentiometric titration. The second possibility utilizes adsorption of UV and visible radiation or luminescence of alkaloids, and is performed by the means of photodensitometry, densitometry and fluorimetry *in situ*. This latter technique requires the use of an optical scanner, which is a relatively expensive piece of equipment.

ALLERGENS IN PERFUMES: GAS CHROMATOGRAPHY- MASS SPECTROMETRY

S. C. Rastogi, National Environmental
Research Institute, Røskilde, Denmark

Copyright © 2000 Academic Press

Perfumes (fragrance substances) are used in the formulation of consumer products to provide pleasure to the user and/or to mask malodours of some other ingredients in the products. Perfumes are also used in aromatherapy. A typical perfume may be composed of 10–300 substances selected from a battery of over 3000 synthetic and natural fragrance materials. It has been shown that approximately 2% of the general population is allergic to perfumes. Furthermore, perfumes have also been shown to be one of the major cause of allergic contact dermatitis from the use of cosmetics and toiletries. Besides cosmetics, the use of many other consumer products such as perfumed laundry detergents and dishwashers have also been implicated as the cause of perfume allergy in contact eczema patients.

Perfume allergy in contact eczema patients is diagnosed by patch-testing with a fragrance mix containing 1% each of geraniol, eugenol, isoeugenol, cinnamic alcohol, cinnamic aldehyde, α -amylcinnamic aldehyde, hydroxycitronellal and an extract from oakmoss – oakmoss absolute. However, only 50–80% of perfume allergy cases are diagnosed by this test. For the management of allergy, it is important to identify the fragrance allergen responsible for contact eczema in a patient, as this makes it possible for the patient to avoid the use of products containing the sensitizing allergen(s). To establish the identity of the fragrance substance responsible for perfume allergy in a contact eczema patient, it is recommended that the product(s) used by a patient should be analysed for the contents of fragrance allergens followed by patch-testing the patient with the relevant fragrance allergens present in the product.

Gas chromatography-mass spectrometry (GC-MS) is frequently used for the analysis of fragrance substances in essential oils. This approach is used for the identification and semiquantitative determination of the fragrance substances of interest in essential oils. In 1995, GC-MS was used for the identification and quantification of 10 selected fragrance substances including the seven chemically defined substances of fragrance mix in perfumes, eau de toilette,

deodorants, creams, lotions, shampoos and other perfumed consumer products which may contain both natural as well as synthetic fragrance materials. The method was later modified slightly so that quantitative analysis of many more fragrance substances in perfumes or in perfumed products could be performed. This method, described in the present article, has been applied to the analysis of perfumes in various consumer products. To demonstrate the potential of the method for perfume analysis, example of analysis of fragrance substances in a deodorant and in an eau de toilette are presented here. Sample preparation methods for the GC analysis of fragrances in various types of consumer products is also described. The quantitative data on fragrance substances in various consumer products are reported in the publications described in the Further Reading section.

Target Fragrance Substances

The analytical method has been developed for the quantification of 21 fragrance substances which in relatively high concentrations are commonly used in the composition of perfumes, or which are established contact allergens:

- 1 geraniol: CAS registration number 106-24-1;
- 2 eugenol: 97-53-0;
- 3 isoeugenol: 97-54-1;
- 4 linalool: 78-70-6;
- 5 linalyl acetate: 115-95-7;
- 6 citronellol: 106-22-9;
- 7 cinnamic alcohol: 104-54-1;
- 8 cinnamic aldehyde: 104-55-2;
- 9 hydroxycitronellal: 107-75-5;
- 10 α -amylcinnamic aldehyde: 122-40-7;
- 11 α -hexylcinnamic aldehyde: 101-86-0;
- 12 α -isomethylionone: 127-51-5;
- 13 coumarin: 91-64-5;
- 14 piperonal: 120-50-7;
- 15 benzyl alcohol: 100-51-6;
- 16 benzyl acetate: 140-11-4;
- 17 benzyl benzoate: 121-51-4;
- 18 benzyl salicylate: 118-51-8;
- 19 Lillal®: 80-54-6;
- 20 Lyrall®: 31906-04-4;
- 21 Hedione®: 24851-98-7.

Approximately 1.0% (w/v) solutions of all of the substances in ethanol served as stock solutions. The stock solutions were stored in closed vials at 4°C and were used within 1 month.

Sample Preparation

Perfumes, Eau de Toilette, Aftershave and Deodorant Sprays

These products were approximately diluted in ethanol so that the concentrations of target fragrance substances were $\leq 0.1\%$. Depending on the concentrations of the target fragrance substances in a sample, it may be necessary to analyse several dilutions of the sample.

Shampoos, Creams, Lotions, Lipsticks, Face Powders and Deodorant Sticks

Perfumes from 1 g sample were extracted in 10 ml methanol at 60°C (to facilitate the extraction) followed by removal of matrix components by silica gel column chromatography. The extract was loaded on a 7 × 1.8 cm silica gel column, and the fragrance fraction was eluted with methanol. The perfume extract was stored at 4°C and analysed within 24 h.

Soap Bar and Laundry Detergents

Perfumes from 1 g sample dissolved in 50 ml water were extracted in 10 ml ethyl acetate employing liquid-liquid extraction. The perfume extract in ethyl acetate was centrifuged to remove any solid or aqueous contamination. The perfume extract was stored at 4°C and analysed within 24 h.

Dishwashing liquid

The method used for the extraction of perfumes from dishwashing liquids was the same as for shampoo.

GC-MS Analysis

MS Conditions

Electron impact ionization at 70 eV was used, scanning m/z 29–250 in 0.6 min.

Results

The method described here has been applied to the determination of 21 target fragrance substances in consumer products. The chromatographic separation of these 21 compounds employing GC is shown in Figure 1. Day-to-day variation of retention times of the fragrance substances is $< 0.5\%$. The detection limits of all of the target substances are ≤ 1 p.p.m.,

the calibration curves for all of the target substances are linear (coefficient of correlation > 0.995) in the tested concentration range 10–2000 p.p.m., the relative standard deviations of the determination of all of the substances are $< 11\%$. The recovery of all of the target substances from the spiked samples is 82–116%, and day-to-day variations of quantitative analysis for all of the substances are within 5%.

The reconstructed ion chromatogram obtained by GC-MS analysis of fragrance substances in a deodorant (undiluted) is shown in Figure 2. The fragrance substances in the product were identified by comparing the retention times of the GC peaks with those of the reference materials, as well as by comparing the spectra of the GC peaks with the reference spectra of standard compounds in the mass spectrum library. Followed by GC-MS identification, quantification of target fragrance substances in the sample is carried out with external standards.

Most consumer products contain many more fragrance substances other than the target compounds. The identification of these substances was only performed by comparing the mass spectrum of a GC peak with the mass spectra of reference compounds in the MS library. In this case, both the spectrum fit and spectrum purity of match of the unknown spectrum with those of library spectra were > 900 . An example of identification of fragrance substances in an eau de toilette is shown in Figure 3A–E, where the results are divided in six windows for the clarity of peak identification. Confirmation of the identification of these substances and their quantification were performed where a reference material was available.

In some cases it is not possible to identify all the peaks because of the absence of mass spectra of the compounds in the mass spectral library.

Discussion

For the analysis of perfumes on a routine basis, GC-MS identification of the fragrance substances followed by quantification employing GC-flame ionization detection (FID) was found to be a more suitable approach. The main reason for this is that the use of GC-FID allows relatively rapid production of validated data. Thus, several relevant analysis recommended by quality assurance/quality control (QA/QC) protocol for a set of samples can be easily performed by GC-FID. Fulfilling the requirements of QA/QC protocol for the analysis by GC-MS is time-consuming, because it requires tuning and calibration of the MS at regular intervals and frequent cleaning of the ion source. The detection limits of the target

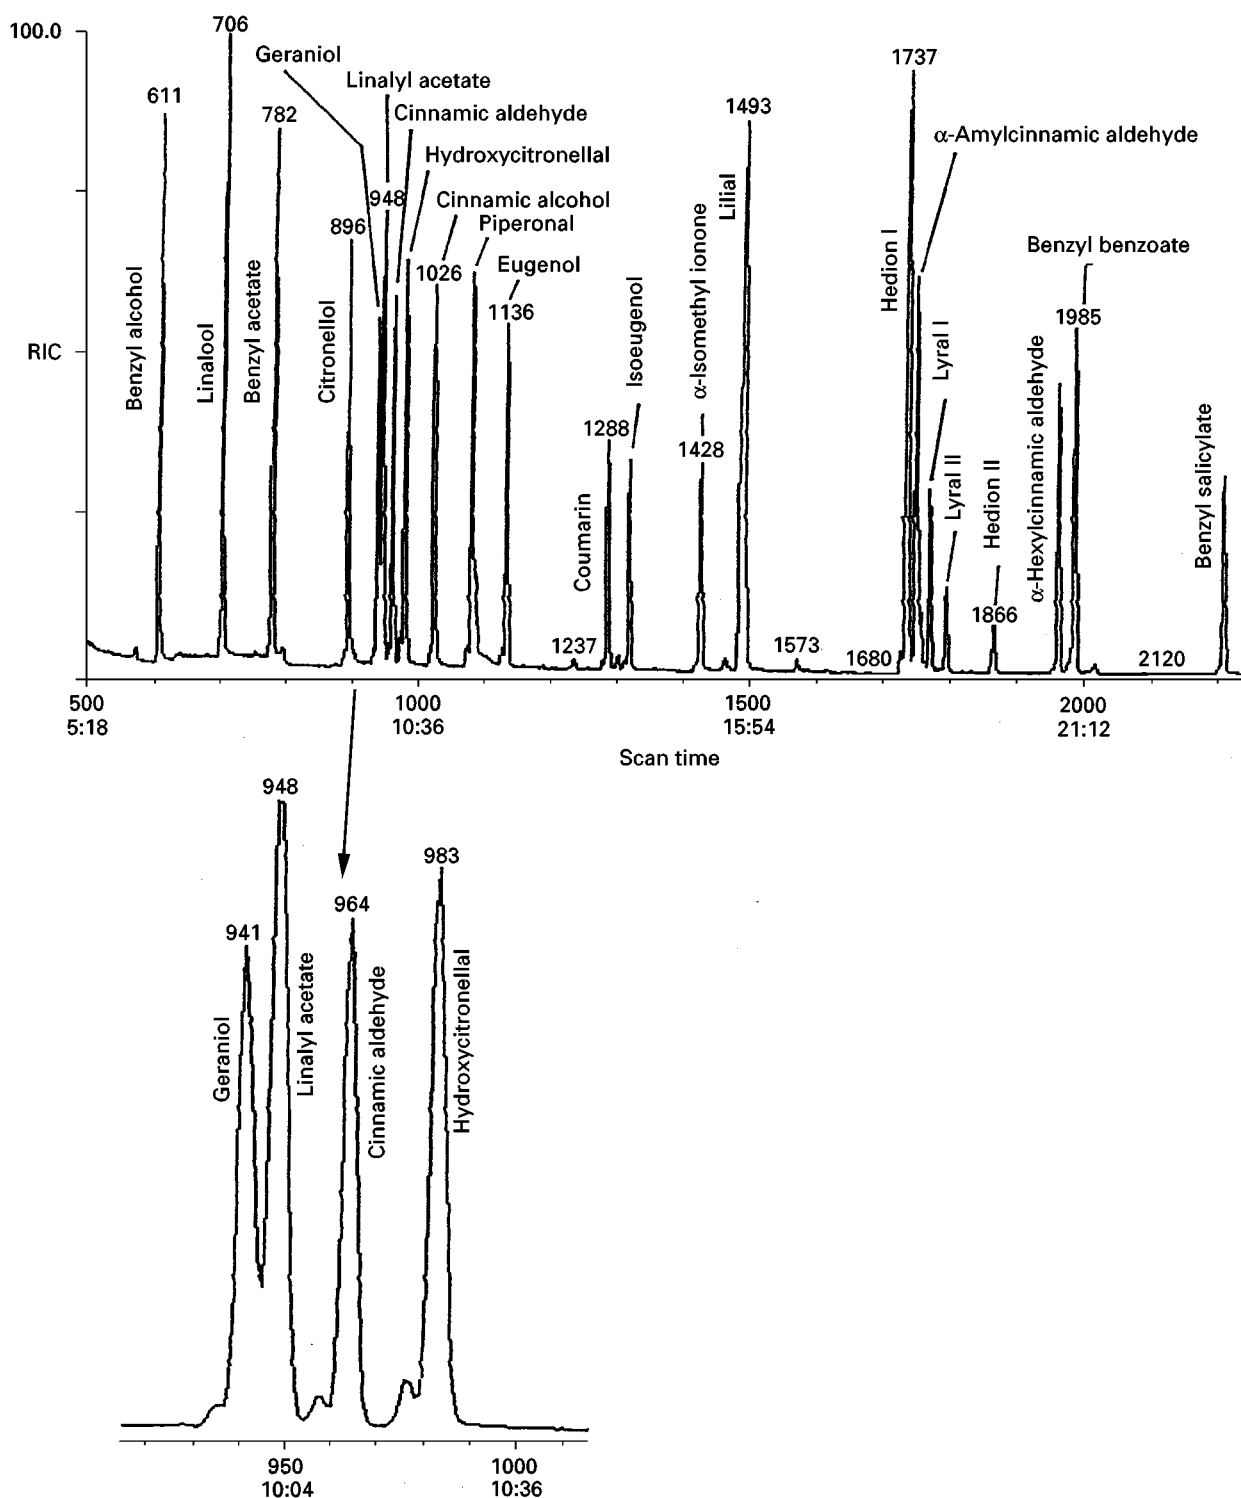

Figure 1 GC-MS analysis of a mixture containing 83–117 p.p.m. of the 21 target fragrance substances. 50 m × 0.32 mm, 1.2 μm film thickness Chrompack fused silica capillary columns coated with CP-Sil-5CB, were used. 1 μL split injection; helium carrier gas flow 30 ml min⁻¹, column-head pressure 20 psi; injector temperature 300°C; column temperature program: 40–140°C in 4 min, thereafter 5°C min⁻¹ to 280°C, 5 min at 280°C. 2 μL injection volume was used when the content of perfume in a sample was relatively low.

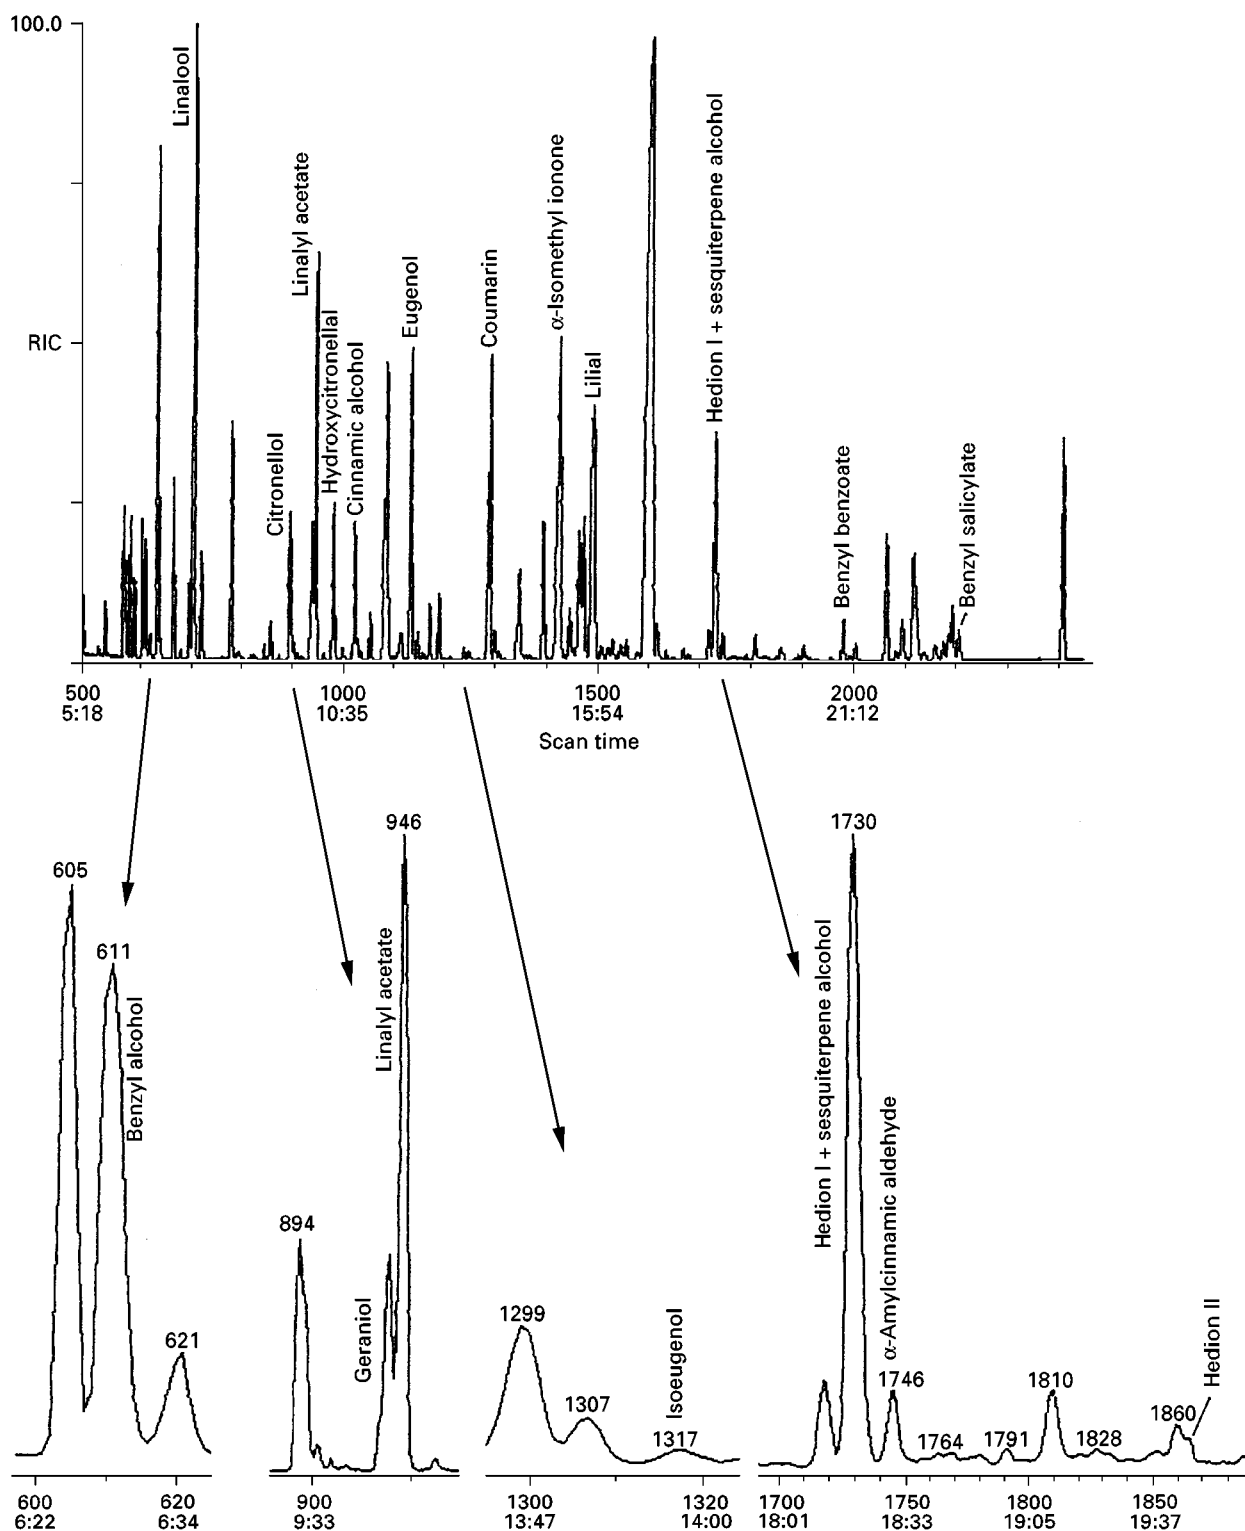

Figure 2 GC-MS analysis of the target fragrance in an undiluted deodorant. The following were present among the target fragrance substances: 102 p.p.m. benzyl alcohol, 1028 p.p.m. linalool, 141 p.p.m. citronellol, 136 p.p.m. geraniol, 614 p.p.m. linalyl acetate, 205 p.p.m. hydroxycitronellal, 183 p.p.m. cinnamic alcohol, 408 p.p.m. eugenol, 1051 p.p.m. coumarin, 7 p.p.m. isoeugenol, 319 p.p.m. α -isomethylionone, 291 p.p.m. Lilial®, 199 p.p.m. Hedion®, 68 p.p.m. α -amylcinnamic aldehyde, 101 p.p.m. benzyl benzoate and 112 p.p.m. benzyl salicylate. Quantification of Hedion® was performed by the analysis of 1 : 10 dilution of the sample, where no interference by the sesquiterpene alcohol present in the sample was observed.

Figure 3 GC-MS analysis of an eau de toilette, diluted 1 : 10 in ethanol. The reconstituted ion chromatogram is divided in six windows (A-F) for the clarity of the compounds identified in the sample. Peaks with no name could not be identified.

Figure 3 Continued

Figure 3 Continued

substances by GC-FID, however, are 2–5 p.p.m. So, unless the quantification was required at 1 p.p.m. level, GC-FID was chosen for the determination of fragrance substances after prior identification by GC-MS.

Most of the fragrance substances in use, including the target fragrance substances, have a molecular weight < 250 Da. Therefore, the MS scan was performed only up to m/z 250. Occasionally, for example in the identification of musk ketone, it is necessary to scan masses up to 300.

Not all the fragrance ingredients in all tested products could be identified or quantified, in some cases due to interferences. Occasionally the GC peak of a relatively high amount of dipropylene glycol present in a sample overlapped the peak by benzyl alcohol; a C_{11} -alkyne interfered with the analysis of Lilial®; high amounts of triethyl citrate and/or a sesquiterpene alcohol ($C_{15}H_{26}O$) interfered with the analysis of Hedione® and relatively high amounts of Hedione® interfered with the analysis of α -amylcinnamic aldehyde. An unidentified compound was found to interfere with the analysis is benzyl salicylate. In most cases these problems could be solved by analysing diluted samples.

By using GC-MS, identification of 226 substances in deodorants has recently been reported. A structure–activity relationship (SAR) analysis of contact allergens revealed that 84 of the identified compounds possess at least one structural alert (chemical group) having sensitizing potential, and 70 belong to, or are susceptible to metabolize into, the chemical groups having sensitizing properties: aldehydes, ketones and α,β -unsaturated aldehydes, ketones or esters. The combination of GC-MS and SAR analysis could be helpful in the selection of substances for supplementary investigations regarding sensitizing properties.

Analysis of as many fragrance ingredients as possible in a perfumed product is of great importance for clinicians to establish the identity of contact allergens in each case. This information is also important for clinical research to investigate cross-reactions of fragrance allergens. The quantitative data on the fragrance ingredients in consumer products make a basis for exposure assessment that is a help for establishing threshold concentrations of fragrances for the elicitation of contact allergy.

Conclusions

Chemical analysis of perfumes and perfumed products is of great importance for the diagnosis and management of perfume allergy. The GC-MS/GC-

FID method described here for the analysis of fragrance substances in consumer products has proved to be valuable to identify allergens in patients with contact eczema from the use of perfumes and perfumed products. Using GC-MS in combination with SAR it has been possible to identify several fragrance substances in perfumes which possess sensitizing potential.

Aliphatic and aromatic mono-, di- and polyamines are naturally occurring compounds formed as metabolic products in microorganisms, plants and animals, in which the principal routes of amine formation include the decarboxylation of amino acids, amination of carbonyl compounds and degradation of nitrogen-containing compounds. Accordingly, amines are important indicators of a wide variety of biochemical, clinical, toxicological and fermentation processes. Amines are also widely used as raw materials or as intermediates in the manufacture of industrial chemicals, e.g. pesticides, medicines, dyestuffs, rubbers, polymers, surfactants, cosmetics and corrosion inhibitors. Many of them are discharged into the atmosphere and water from anthropogenic sources such as foods, cattle feeds, livestock buildings, waste incineration, sewage treatment, automobile exhaust, cigarette smoke and various industries. Furthermore, many amines have an unpleasant smell and are hazardous to health as sensitizers and irritants to the skin, eye, mucous membranes and respiratory tract. Some amines are also suspected to be allergenic, mutagenic or carcinogenic substances due to their adsorption in living tissue. Amines are not only toxic of themselves but can also become toxic *N*-nitrosamines through chemical reactions with nitrosating agents such as nitrite or nitrate.

Gas chromatography (GC) has been widely used for amine analysis because of its inherent advantages of simplicity, high resolving power, high sensitivity, short analysis time and low cost. In addition, a wide variety of detectors can be used: nitrogen-phosphorus (NPD), electrolytic conductivity (ELCD) and chemiluminescent (CLD) detectors offer increased selectivity for specific amines. Furthermore, the combined technique of GC-mass spectrometry (MS) can provide structural information for the unequivocal identification of amines. Sub-nanogram detection limits can be achieved using these detectors. However, GC separation of free amines at very low concentrations generally has inherent problems related to the difficulty in handling low molecular

mass amines because of their high water solubility, high volatility and ready oxidation under chromatographic conditions. Furthermore, amines tend to be strongly adsorbed and decomposed on the columns and give tailing peaks, ghosting phenomena and low detector response. The adsorption tendency in the analytical system, i.e. in sample vessels, injector, glass wool and GC column, is in the order primary > secondary > tertiary amines, and tailing becomes increasingly severe as the basicity of the amines increases. In addition, it is generally more difficult to chromatograph aliphatic than aromatic amines.

A common method of overcoming these problems is to convert such polar compounds to relatively non-polar derivatives more suitable for GC analysis. A number of derivatives such as acyl, silyl, dinitrophenyl, permethyl, Schiff base, carbamate, sulfonamide and phosphonamide compounds have been used for this purpose.

Another successful approach has been to employ less reactive column packing materials to reduce the interaction with solutes, for example, the use of porous polymers and the deactivation of supports by treatment with alkali. Wall-coated (WCOT), support-coated (SCOT) and porous-layer (PLOT) open tubular capillary columns, which minimize column-solute interactions, have also been used for this purpose. Free amines can be analysed after addition of alkali, either by direct injection or by headspace sampling, or they can be extracted into an organic solvent before analysis. Direct or headspace analysis of samples minimizes sample preparation, thereby reducing the possibility of contamination. Solid-phase microextraction (SPME), with integrated sampling, extraction, concentration and sample introduction in a single step, has recently been used for amine analysis by coupling with GC.

This article is concerned with the general aspects of direct GC separation of underivatized aliphatic and aromatic amines, and various characteristics with respect to columns are considered in more detail below.

Column Development

Packed-column GC is generally simpler to set up than capillary GC, because of the ability to apply the stationary phase easily to the solid support and modify it appropriately to the particular analysis

required. Deactivation of the glass surface can be effected using a suitable silylating reagent to limit the effect of adsorption on the wall of the column. However, the general difficulty in the chromatography lies in absorptivity on the solid support leading to tailing. The adsorption of amines by the support material has been attributed to the presence of free silanol groups on the silica surface participating in hydrogen bonding with the free electron pair of the nitrogen atom of the amine. Simple treatment with KOH reduces the adsorption to a minimum, allowing good peak shape and optimum performance.

Glass and fused silica capillary columns have also been used for the analysis of free amines. The inherent strength and flexibility of fused silica make it easier to use and less fragile than glass capillary columns. Furthermore, fused silica provides a more inert surface for improved performance and less adsorption. The analysis of free amines on packed columns has now largely been replaced by analysis on fused silica capillary columns that are commercially available with a range of stationary phases. The packed and capillary GC columns reported in the past 30 years for amine analysis are summarized in Tables 1 and 2.

Packed Columns

Three types of packing can be used to separate amines: graphitized carbon coated with a stationary phase and deactivated, coated and uncoated porous polymers, and conventional columns packed with a deactivated diatomaceous earth coated with a sta-

tionary phase. The columns are usually deactivated with KOH, trimethylchlorosilane (TMCS) or ammonia in the carrier gas. Carbowax graphitized carbon and porous polymer packings are well suited for separating C_1 – C_{10} compounds, but retention times for larger molecules are excessive; deactivated and coated conventional packings are better suited to the analysis of higher molecular weight amines.

Graphitized carbon packings Graphitized carbon packings are generally used for free amine analysis after coating with a stationary phase. Sterling FT-G and Vulcan, sold by Supelco as Carbowax A and Carbowax B, respectively, have been used for the analysis of C_1 – C_{16} aliphatic amines with suitable amounts of KOH and polyethylene glycol (PEG), e.g. PEG 20M and PEG-1500. A 4.8% PEG 20M/0.3% KOH on Carbowax B column is recommended for the analysis of C_1 – C_4 aliphatic amines in aqueous solution at nanogram level. This column offers complete separation of the C_2 – C_3 amine isomers and is less affected by water than the other packed columns. However, the preparation of the column seems to be difficult for routine analysis. A 1.5% UCON 50-HB-2000 on Carbowax B packing deactivated with 0.8% KOH has also been used to separate a mixture of aliphatic, aromatic and cyclic amines, and rapid separation of nine amines without ghosting was obtained by temperature programming and treatment of glass wool in the column ends with dimethylchlorosilane (DMCS). On the other hand, 4% Carbowax 20M on 0.8% KOH-deactivated Carbowax B packing has

been specifically developed for monitoring low molecular weight aliphatic amines at p.p.m. levels in water. Heterocyclic amines can also be separated on this packing, but aromatic amines exhibit excessively long retention times. By using this column and an NPD, low molecular weight amines in sea water were determined. In order to reduce the appearance of ghost peaks, 15% ammonia solution was injected on to the hot (150–200°C) column after each sample run. As shown in **Figure 1**, 23 amines were separated within 25 min (**Figure 1A**), and 12 amines were selectively detected in sea water (**Figure 1B**).

A general characteristic of Carbowax-based columns is that sample components are separated by carbon number and are eluted in the order $C_1 \rightarrow C_2 \rightarrow C_3$, and so forth. This is seen in the separation of methylamine, dimethylamine, trimethylamine and ethylamine. Both C_2 amines (dimethylamine and ethylamine) are eluted before the C_3 amine (trimethylamine). On these packings, it is necessary to use small samples to prevent tailing due to overloading. Furthermore, the column must be conditioned by injecting a number of relatively large amounts of water when analysing amines in aqueous solution. This treatment converts any K_2CO_3 in the column to

KOH, making the column more basic and improving its inertness for amines. Acidic compounds in the sample are irreversibly adsorbed by the KOH. In addition, a certain amount of stationary phase is hydrolytically decomposed and appears as a water peak in the chromatogram when water passes through the column. Therefore, conditioning is needed to clean the column and minimize the water peak when standards and sample are subsequently injected. These packed columns should not be exposed to air, since the packing will adsorb carbon dioxide and lose its deactivation. Furthermore, the water used should be distilled or deionized, and freshly boiled to remove CO_2 .

Porous polymer packings Porous polymers possessing large surface area are often used as column packing in GC without coating with a stationary phase. Tenax GC and Chromosorb 103 were specifically developed to separate low molecular weight aliphatic amines. Although Chromosorb 103 proved inconsistent and difficult to handle, and tended to expand on heating, leaving gaps in the column upon cooling, these effects could be minimized by paying scrupulous attention to packing. By using Chromosorb 103,

Figure 1 (A) Amine standards and (B) a sea water sample. GC conditions: packed column, 4% Carbowax 20 M and 0.8% KOH on Carbowax B ($2\text{ m} \times 2.5\text{ mm i.d. glass}$); column temperature, initially hold at 85°C for 2.5 min, increase to 150°C at $32^\circ\text{C min}^{-1}$ for 6 min and then to 220°C at $10^\circ\text{C min}^{-1}$; injector and detector temperatures, 200 and 220°C , respectively; He carrier gas flow rate, 22 mL min^{-1} ; detector, NPD. Peaks: 1, ammonia; 2, monomethylamine; 3, dimethylamine; 4, ethylamine; 5, trimethylamine; 6, 2-propylamine; 7, 1-propylamine; 8, *tert*-butylamine; 9, diethylamine; 10, *sec*-butylamine; 11, 2-butylamine; 12, pyrrolidine; 13, 1-butylamine; 14, piperidine; 15, triethylamine; 16, pyridine; 17, 2-amylamine; 18, 1-amylamine; 19, pyrrole; 20, dipropylamine; 21, cyclohexylamine; 22, tripropylamine; 23, dibutylamine. (Reproduced with permission from Yang *et al.* (1993) *Analytical Chemistry* 65: 572.)

11 aliphatic amines were isothermally separated without the ghosting observed with alkali-washed support packings. The use of longer columns resulted in increased analysis time that could not be reduced with a higher final temperature owing to excessive column bleed. Amines tail on other porous polymers, but performance can be improved by coating them with a stationary phase and TMCS. By using 5% squalene/2% KOH on Chromosorb 103 or 104 and GC-CLD, low molecular weight aliphatic amines have been determined. A column packed with Chromosorb 102 treated with 5% TMCS and coated with KOH has been used to determine methylamines in biological materials at low concentration by headspace GC-NPD. Use of headspace sampling avoids the possibility of interference from other water-soluble biological substances.

Partition columns A partition column consists of a support, generally a diatomaceous material, coated with a stationary phase. However, the support tends to interact with active analytes, such as amines, caus-

ing the peaks to tail, unless it is made strongly basic by adding KOH or an amine or by using an amine as the stationary phase. This alkaline deactivation of diatomaceous supports appears to be more effective than silanization for the analysis of amines. The major disadvantage of alkali-washed packings lies in the thermal instability of the liquid phases that prevents temperature-programmed analysis. Generally, Chromosorb W (white and light weight) and Chromosorb P (pink) supports are used as support materials; polytetrafluoroethylene supports are widely regarded as very inert, but they do not appear to be especially inert to amines. The stationary phase must be compatible with the basic material. Polyglycols, such as Carbowax and certain hydrocarbons, have been used successfully with basic materials.

Although a 10% Carbowax 20M/2% KOH on Chromosorb W AW packing was used for separating aliphatic mono- and diamines, many of the higher boiling anilines apparently did not elute from the column. Other PEG packings, such as PEG-1000 on Chromosorb G and PEG-HT on Uniport HP, have

also been used for the analysis of aliphatic and aromatic amines. Di- and polyamines in tissue samples were analysed using Corning glass beads coated with 4% Carbowax and 1% KOH. This column gave a good separation and a nearly complete recovery of these amines.

Aromatic amines are generally less basic than aliphatic amines and consequently present less of an adsorption problem. Although they can be separated on the highly basic columns described above, the analysis is generally carried out with a silicone stationary phase on an acid-washed, dimethylchlorosilane (AW-DMCS) treated support. The SP-2250 and SP-2401-DB packings were specially developed for separating amines at low concentrations. When analyte concentrations are very low, even AW-DMCS treatment is inadequate, and it is necessary to use a specially deactivated column or derivatize the analytes. The 3% SP-2250 column partially resolved all the anilines, but some peak tailing was evident, especially for aniline. The 5% SP-2401-DB (containing KOH) and 1.5% SP-2250/1.95% SP-2401 gave no improvement in peak shape, in spite of the greater polarity, compared to SP-2250. In addition, several compounds were not resolved on these columns. The Silar 5CP column partially resolved all the anilines except for 3- and 4-chloroanilines, and gave good peak shape for all the compounds. As shown in Figure 2, the best separation of 19 anilines was obtained using a 3% SP-2250 on Supelcoport.

Capillary Columns

Capillary columns offer a significant improvement in separation, in comparison to conventional packed columns, and have been used for the separation of complex mixtures and components closely related chemically and physiologically. As shown in Table 2, various glass and fused silica capillary columns have been used for free amine analysis. Fused silica capillary columns provide strength, flexibility and a more inert surface for improved performance and less adsorption. Cross-linked or bonded-phase columns can be washed with solvents, prolonging their lifetime. Furthermore, the advance of commercially available cross-linked and bonded-phase capillary columns and precise temperature-controlled GC ovens has meant that the retention times are extremely reproducible. This is critical when using automated data-handling equipment for identification and quantification. Typically, 10–30 m long columns, coated with either non-polar or polar stationary phases, have been used for amine analysis. Many of the phases used today are specifically manufactured by the column supplier, and give excellent performance, low bleed and high efficiency. However, there is the drawback that a col-

Figure 2 Aniline compounds on packed column. GC conditions: column, 3% SP-2250 on Supelcoport (1.83 m \times 2 mm i.d. glass); column temperature, 4°C min⁻¹ from 80 to 230°C; injector and detector temperatures, 250 and 300°C, respectively; He carrier gas flow rate, 30 mL min⁻¹; detector, NPD. Peaks: 1, aniline; 2, 2-chloroaniline; 3, 3-chloroaniline; 4, 4-chloroaniline; 5, 4-bromoaniline; 6, 3,4-dichloroaniline; 7, 2,4,6-trichloroaniline; 8, 2-nitroaniline; 9, 2,4,5-trichloroaniline; 10, 3-nitroaniline; 11, 4-chloro-2-nitroaniline; 12, 4-nitroaniline; 13, 2,6-dichloro-2-nitroaniline; 14, 2-chloro-4-nitroaniline; 15, 2-bromo-6-chloro-4-nitroaniline; 16, 2,6-dibromo-4-nitroaniline; 17, 2-chloro-4,6-dinitroaniline; 18, 2,4-dinitroaniline; 19, 2-bromo-4,6-dinitroaniline. (Reproduced with permission from Riggins *et al.* (1983) *Analytical Chemistry* 55: 1862.)

umn from one supplier may not give the same separation as the nominally equivalent column from another supplier.

Glass capillary columns In early work, glass capillaries were employed for the separation of aromatic amines using alkaline PEG as the stationary phase. Although a disadvantage of this phase is its tendency to deteriorate at temperatures slightly above 200°C, it has been used for the separation of methylanilines and methylpyridines in coal-tar light oil. Carbowax 20M columns have been used for the determination of airborne aromatic amines with an NPD. The necessary inertness of glass capillary columns may be achieved by deactivation with octamethylcyclotetrasiloxane (OMCTS). The glass or fused silica columns were silanized using OMCTS and trifluoropropyl(methyl)cyclosiloxane, and coated with various phases (SE-30, SE-52, SE-54). Test mixtures containing about 1 ng of such difficult substances as primary mono- and diaminoalkanes gave symmetrical peaks on some of these phases. As shown in

Figure 3 Drug standard mixtures on (A) AR glass and (B) fused silica capillary columns coated with SE-54 and with flame ionization detector. Temperature programmes are shown within the figure. Peaks: 1, amphetamine; 2, phentermine; 3, propylhexedrine; 4, methamphetamine; 5, ethylamphetamine; 6, propylamphetamine; 7, ephedrine; 8, phenmetrazine; 9, phendimetrazine; 10, amfetramone; 11, benzocaine; 12, phenacetin; 13, methyl phenidate; 14, procaine; 15, methaqualone; 16, cocaine; 17, codeine; 18, ethylmorphine; 19, morphine. (Reproduced with permission from Blomberg *et al. Journal of Chromatography* 239 (1982) 51).

Figure 3, the separation of some underivatized drugs is equally good on alkali-resistant (AR) glass and fused silica capillaries, although alkali-resistant (AR) glass has a basic character that can be reduced by careful leaching.

On the other hand, interesting results dealing with the separation of free amines and other nitrogen compounds were reported in glass capillary columns with stationary phases polymerized *in situ*.

Fused silica capillary columns For the analysis of amines, capillary columns with a nonimmobilized PEG-type stationary phase have been specially prepared and are commercially available. For the analysis of volatile amines, aromatic and heterocyclic amines and other amino substances, CAM, CP-Wax, HP-20M, Carbowax 20M and Carbowax Amine capillary columns have been recommended. These columns are generally deactivated with KOH to elute basic compounds with good peak shapes and responses. Three types of fused silica capillary columns, Supelcowax 10 (PEG), CP-Sil-19CB (methylphenylcyanopropylsilicone) and HP-1 (methylsilicone) have also been used for the separation of aliphatic and aromatic amines. Ammonia as a carrier gas can dras-

tically affect the retention factors and improve the peak symmetry for aliphatic amines. A porous polymer fused silica capillary column, PoraPLOT Amine, has been used to separate very volatile amines. By using this column and ELCD, C_1 – C_6 amines in aqueous and methanolic solution were analysed. The separation of aniline and its halogen and nitrogen derivatives in waste water were evaluated using several glass and fused silica capillary columns of polysiloxane type (SE-30, SE-52, SE-54, SP-2100) and NPD. Each of the capillary columns gave excellent peak shape for all the anilines, but failed to resolve at least one compound pair (e.g. the SE-30 completely resolved 3- and 4-chloroaniline that co-eluted on SE-54, but failed to resolve the 2,6-dibromo-4-nitroaniline and 2,4-dinitroaniline which were completely resolved on SE-54). Figure 4 shows a chromatogram of an aniline mixture on an SE-54 fused silica column. The NPD sensitivities for many anilines are substantially better with the SE-54 capillary column (Figure 4) than with the 3% SP-2250 packed column (Figure 2), primarily because less peak tailing is observed at low concentration. Interestingly, the fused silica and glass capillary SE-54 columns gave different elution patterns for the various anilines. Using both SE-54 and SE-30

fused silica capillary columns, all 19 anilines can be resolved.

A polysiloxane capillary column specially designed for the analysis of basic compounds using new deactivation technologies has been developed. This proprietary deactivation provides both the inertness (basicity) and surface energies required to coat a 5% diphenyl/95% dimethylpolysiloxane stationary phase successfully. Using this column, C₃–C₁₀ primary amines can be separated as symmetrical peaks. This column allows lower limits of detection for basic compounds such as substituted anilines and benzidines. Since the column is virtually identical in polarity to the widely used ordinary columns with the same stationary phase, it can be directly substituted and run under the same temperature conditions. DB-5ms and DB-35ms columns certified for use with MS have been developed for the analysis of aliphatic and aromatic amines. These columns have very low bleed characteristics and excellent inertness. As shown in **Figure 5**, 17 aromatic amines were completely separated using a DB-35ms column.

Lower aliphatic tertiary amines in environmental samples were analysed by headspace GC with a mass selective detector (MSD) using a polymethylsiloxane column. The SPME method has gained popularity as a solvent-free, reliable and flexible tool for sampling a variety of volatile and semi-volatile compounds. By combining SPME with GC, these compounds can be simply and rapidly extracted, concentrated and introduced into the GC system. Using headspace SPME and GC-MSD on polysiloxane-type fused silica capillary columns such as DB-1, OV-1, SPB-1, HP-1 and HP-5, amphetamine, methamphetamine and related

stimulants in urine can be analysed at the ng mL⁻¹ level. Recently, headspace SPME and GC-NPD using a slightly polar capillary column CBJ-17 (**Figure 6**) has developed as a method for determining amphetamines in human hair.

Future Prospects

Much of the early work on the separation of free amines was done with columns packed with PEG and KOH on diatomaceous earths. Although this approach was reasonably successful, the analysis of free amines on packed columns has now largely been replaced by analysis on fused silica capillary columns. Application of capillary columns is expected to increase as further developments in these columns, e.g. shorter inactive columns with smaller internal diameters giving ultra-high column efficiency and speed, higher temperature phases and exterior coating for the fused silica tubing, permit the analysis of both high temperature and highly volatile amines. Furthermore, simple, rapid and automatic analysis of free amines in various samples will be achieved by combination with convenient sample preparation techniques such as SPME.

During the 1950s and 1960s, significant progress was made in the development of automated amino acid analysers based on separation by ion exchange. However, such instruments were dedicated to the task of amino acid analysis and were of limited application to the analysis of other types of compounds. Furthermore, they were expensive. During the same period, gas chromatography (GC) was being rapidly developed following the demonstration in 1952 by James and Martin that fatty acids could be assayed by GC. There followed a vast expansion in the application of GC to the analysis of other types of compounds. Amino acids were a logical target. In the intervening years, methods have been developed for assaying amino acids in protein hydrolysates and physiological fluids, and for determining the proportions of amino acid enantiomers in racemic mixtures. Some landmark developments are listed in Table 1.

Proteic and Physiological Amino Acids

Derivative Development

Amino acids are not sufficiently volatile or stable at the temperatures required for analysis by GC. Thus, they must be converted to derivatives having the desired characteristics. It was to be no simple task to derivatize or mask the several functional groups in even the 20 proteic amino acids. Carboxy, amino,

hydroxy and sulfhydryl groups all need to be converted to eliminate internal zwitterionic charges and hydrogen bonding, and thus increase the volatility of the derivatives. It was thought in those early years that the molecular mass also required to be reduced but it was later realized that this was not an absolute requirement. As new reagents became available, it was found that volatility could be significantly increased while increasing the derivative mass. Apart from the multiplicity of functional groups, it is also necessary that each group should be quantitatively converted.

The first report of amino acid analysis by gas liquid chromatography was published in 1956. Hunter, Dimick and Corse oxidized isoleucine and leucine with ninhydrin to form volatile aldehydes. These were resolved using a 10 ft long silicone oil–celite column operated isothermally at 69°C. Peaks were detected at about 44 and 48 min (**Figure 1**). The aldehydes were generated using 2–5 mg of each amino acid. Either of the leucines could be assayed in the presence of 10-fold quantities of the other. However, only about eight simple amino acids yield volatile aldehydes.

From this simple but momentous beginning, there followed, in the next two decades, a proliferation of reaction schemes to prepare stable, volatile amino acid derivatives. Various oxidation, hydrocracking, pyrolysis and reduction reactions were explored but significant progress was to evolve from those procedures which focused on substituting the exchangeable protons of the reactive groups. In 1957, Bayer, Reuther and Born separated glutamic acid, leucine, methionine, norleucine, norvaline, phenylalanine, sarcosine and valine methyl esters on a silicone oil–sodium caproate packing. The use of an acyl ester constituted the first report of a key component in

Table 1 Advances in gas chromatography of amino acids

1956	First GC analysis (Hunter, Dimick and Corse)
1959	Acyl amino acid alkyl esters separated (Youngs)
1965	Resolution of alanine, leucine and valine enantiomers (Gil-Av, Charles and Fischer)
1962–79	Development of derivatization and separation procedures for the proteic amino acids (Gehrke)
1971	First single column separation of all proteic amino acids (Moss, Lambert and Diaz)
1971–76	Further improvements in resolution
1977	Development of Chirasil Val® (Frank, Nicholson and Bayer)
1989	Use of cyclodextrins for enantiomer resolution (König, Krebber and Mischnick)
1991	4 min analysis of proteic amino acids (Hušek)

a derivatization strategy which would eventually prove to be successful. One year later, Bayer reported that good resolution could be achieved using *N*-trifluoroacetyl (TFA) amino acid esters. This work represented the first use of *N*-TFA derivatives, representatives of a class of compounds which would feature strongly in later developments.

In the next decade, *N*-formyl and -acetyl derivatives were combined with a variety of alkyl esters such as methyl, ethyl, propyl, isopropyl, isobutyl, amyl and isoamyl. The work of Youngs in 1959 was the first in which *N*-acyl derivatives were combined with alkyl amino acid esters. *N*-acetyl ethyl and butyl esters of six simple amino acids were separated on

hydrogenated vegetable oil. This approach was to provide the foundation for developments leading, over the next several years, to the quantitative resolution of all the amino acids in a protein hydrolysate. In 1964 Karmen and Saroff showed that excellent yields of *N*-TFA amino acid methyl esters were obtained when the esters were first prepared and then acylated. This general protocol remains in use.

The use of *N*-TFA derivatives in combination with amino acid alkyl esters was first reported by Ettre in 1962. Starting in the same year, Gehrke and his colleagues systematically studied the derivatization and chromatography of the *N*-TFA *n*-butyl amino acid esters. TFA derivatives were used in amino acid chemistry by Weygand as early as 1952 but were first applied in the context of GC analysis in 1960. In the first report, 22 naturally occurring amino acid derivatives were resolved in less than 45 min using a 2 m column packed with Gas Chrom A coated with 1% neopentyl succinate. Subsequently, the esterification reaction was simplified by using direct esterification instead of methylation followed by interesterification. Direct on-column injection and an all-glass system were demonstrated to avoid degradation of some derivatives. Rigorous exclusion of water is necessary both for complete derivatization and to prevent hydrolysis of derivatives once formed. These and other procedures developed by Gehrke formed a solid quantitative foundation for subsequent studies by others.

Continued refinement of both the reaction chemistry and the columns culminated in the complete separation of the 20 proteic amino acids in 1971. Seventeen amino acids were resolved using a 4 mm i.d. × 1.5 m glass column packed with 0.65% ethylene glycol adipate (EGA) on 80–100 mesh Chromosorb W-AW. The derivatives of arginine, histidine, tryptophan and cystine were separated from those of the other amino acids on a 4 mm i.d. × 1.5 m glass column packed with a mixed stationary phase of 2% OV-17 and 1% OV-210 coated on 100–200 mesh Supelcoport. In particular, histidine could be directly assayed. The two columns were operated simultaneously, resulting in an analysis time of 15–30 min. In 1979, the same derivatives were separated on a single EGA liquid phase but no significant improvement over other available procedures was obtained.

Gehrke also conducted a thorough assessment of possible sources of contamination. As detection sensitivity increased, contamination became a significant problem. At the nanogram level, contamination was shown to derive from laboratory reagents such as butanol, methylene chloride and water, and from human sources such as dandruff, fingerprints, hair, saliva and skin fragments.

Figure 1 Separation of 3-methylbutanal and 2-methylbutanal using a 10ft column filled with a silicone-celite mixture. (Reproduced with permission from Hunter IR, Dimick KP and JW Corse (1956) Determination of amino acids by ninhydrin oxidation and gas chromatography. *Chemistry and Industry* 294–295.)

The stationary phases used during the early years of development fell into three main classes: silicones, polyglycols and polyesters. Because it was difficult to separate even the proteic amino acids on a single phase, mixed phases were common. Eventually, however, the silicone phases, in nonpolar or slightly polar forms, became favoured and were essential for quantitative elution of arginine, cystine and histidine derivatives. Dual- and triple-column procedures were to give way in the search for a single column separation of the proteic amino acids. The first such resolution was achieved in 1971 by Moss, who prepared the *N*-heptafluorobutyl (HFB) *n*-propyl esters. These were resolved on a 10 × 1/4 in glass column packed with 3% OV-1 coated on 80–100 mesh HP Chromosorb W (Figure 2). No quantitative data were provided. There followed other variations on the same theme. The *N*-HFB isoamyl (1973), isobutyl (1974) and isopropyl (1979) esters provided similar resolutions but with subtle separatory advantages depending on the relative proportions of specific amino acids present. Resolution was primarily a function of the ester, while the acyl group mainly moderated the volatility.

The search for a single-column resolution of the proteic amino acids was paralleled by a search for a single reaction which would derivatize all the functional groups present in amino acids. Trimethylsilylation was introduced as early as 1961 by Rühlman and Giesecke who reacted trimethylchlorosilane with amino acid salts. Six amino acids were separated in less than 30 min. A fuller account in 1963 reported that tyrosine and histidine derivatives tended to decompose in the presence of moisture or oxygen. The early reagents were generally silylated amines or monosubstituted amides and double derivative formation was a significant problem. However, newer

reagents, for example *bis*-(trimethylsilyl)trifluoroacetamide, were considerably more potent and derivatization became quantitative. In more recent work (1993), all 22 proteic amino acids, including glutamine and asparagine, which would not be present in protein hydrolysates, have been quantitatively resolved as the *N*(*O*)-*tert*-butyldimethylsilyl derivatives in 41 min on a DB-1 column. The derivatives are formed in 30 min at 75°C.

Other approaches have also been used in the search for the simplest derivatization commensurate with reproducibility and stability, and with good chromatographic characteristics. Reaction with dichlorotetrafluoroacetone forms stable 2,2-*bis*(chlorodifluoromethyl)-4-subst-1,3-oxazolidine-5-one derivatives. All the proteic amino acids and more than 30 other α -amino acids have been studied. However, a second reaction with HFB anhydride is required and analysis of the diaminodicarboxylic acids histidine and tryptophan required a second column.

Alkoxy carbonyl alkyl esters, specifically the isobutoxycarbonyl methyl esters, were first prepared by Makita in 1976. Twenty proteic amino acid derivatives were separated using a dual-column system but the derivatization procedure involves multiple extraction. Arginine was first converted to ornithine. At that time, this procedure offered no significant advantage over the other protocols available. However, the method was subsequently improved so that, in 1996, all the proteic amino acid derivatives were resolved as single peaks in 9 min using a DB-17 capillary column. Serum amino acids could be assayed without any prior clean-up except for deproteinization. The isobutoxycarbonyl derivatives have also been effectively combined with *tert*-butyldimethylsilyl esters.

Figure 2 Separation of *N*(*O*, *S*)-heptafluorobutyl *n*-propyl amino acids. (Reproduced with permission from Moss CW, Lambert MA and Diaz FJ (1971) Gas-liquid chromatography of twenty protein amino acids on a single column. *Journal of Chromatography* 60: 134–136.)

Figure 3 Analysis of *N*(*O*, *S*)-ethoxycarbonyl amino acid ethyl esters on a 10 m × 0.25 mm i.d. capillary column coated with OV1701. (Reproduced with permission from Hušek P and Sweeley CC (1991) Gas chromatographic separation of protein amino acids in four minutes. *Journal of High Resolution Chromatography* 14: 751–753.)

In 1991, Hušek prepared derivatives in the same general class but using ethyl chloroformate which reacts with all the functional groups found in amino acids. The *N*(*O*, *S*)-ethoxycarbonyl ethyl esters are formed in seconds in an aqueous medium. The derivatives were resolved in less than 5 min using a moderately polar OV1701 capillary column (Figure 3).

A variety of derivatization options are now available. The *N*-HFB isoamyl, isobutyl or isopropyl esters are equally effective for the relatively simple task of assaying the standard proteic amino acids. However, procedures requiring only a single derivatization step are more convenient and are preferred. Either the isobutoxycarbonyl methyl esters or the ethoxycarbonyl ethyl esters can be quickly prepared and resolved in less than 10 min using moderately polar capillary columns.

The several hundred amino acids which are present in physiological fluids cannot be resolved by any single method. Each method has advantages in a specific context. Frequently, however, the target is a single or a few structurally related amino acids. In such a context, any of the methods cited above may be appropriate, depending on the specific separations required. However, methods based on alkoxycarbonyl alkyl esters are more convenient to implement. Furthermore, some physiological samples, such as sera, can be assayed directly after deproteinization.

Very few amino acids are not amenable to being analysed by GC. Furthermore, the resolving power of capillary column chromatography cannot be matched by any other separatory medium. GC remains the

method of choice for assaying amino acids in complex physiological samples.

Resolution of Optical Isomers

The determination of the configuration of amino acids and the relative proportions of the *D* and *L* forms is important in both natural and synthetic contexts. Proteins in living organisms commonly contain only the *L*-amino acids but *D*-amino acids occur in antibiotics (e.g. antiamoebin, gramicidin, valinomycin), bacterial cell wall peptidoglycans and in animals and insects. They have also been detected in human urine and blood. On death, the *L*-amino acids racemize, but so slowly that a racemic mixture is only produced over a geological time scale. The racemization rate is a function of temperature and the structure of each amino acid. Aspartic acid, which has a racemization half-life of about 15 000 years at 20°C, is most commonly used for archaeological dating, but there is considerable controversy over the results obtained.

Animal bones and shells and certain sediments contain proteins, for example, collagen and conchiolin. Extraction of the residual protein and determination of the enantiomer ratio of aspartic acid following hydrolysis can, when combined with knowledge of the thermal history of the sample, be used to determine the age of the fossil. Racemization age dating is generally more sensitive and less expensive than the radiocarbon method. Typical examples of the use of this technique have been analysis of Apollo 12 lunar material and dating of the Dead Sea scrolls.

Amino acids also racemize under various conditions such as prolonged acid hydrolysis and during solid-phase peptide synthesis. Chemical procedures such as asymmetric synthesis require proof of enantiomeric purity, especially if the product is to be used for pharmaceutical purposes. Configurational analysis of peptide antibiotics and establishing retention of configuration during peptide synthesis are other contexts in which it is important to determine the enantiomeric composition of amino acid samples.

Enantiomeric amino acid mixtures are resolved using two approaches. The first is to derivatize (acylate or esterify) with optically active reagents to form diastereoisomers or diastereomers which are resolved on an optically inactive stationary phase. The reagents must be of high optical purity and conversion must be quantitative. The second approach is to derivatize with optically inactive reagents, for example the *N*-TFA isopropyl esters, and then conduct the separation on columns containing optically active stationary phases.

Most amino acid optical isomers result from asymmetry at the α -carbon atom and depend on the presence of an α -hydrogen atom. However, some contain two optically active centres. Thus, the *threo* and *erythro* forms of the hydroxy amino acids and isoleucine and *allo*-isoleucine can be resolved on conventional columns. Similarly, isovaline, which contains one asymmetric centre but no α -hydrogen, has also been resolved. The mechanism has been postulated to depend on the formation of transient diastereomeric hydrogen-bonded association complexes but other factors such as dipole-dipole interactions and dispersion forces may also play a role.

Resolution of Diastereomers

All four diastereomers cannot be resolved using optically inactive stationary phases: the DD + LL and DL + LD enantiomer pairs usually coelute. The elution order depends on the specific derivatives. A diastereomer can be formed by esterification or by acylation.

Optically Active Esterification Reagents

Initial studies focused on forming active esters of *N*(*O*)-acyl amino acids and these were subsequently to be the most widely used derivatives. In 1965, Gil-Av reported the first resolution of amino acid diastereomers by GC (Figure 4). The 2-butyl and 2-octyl amino acid esters of alanine, glutamic acid, leucine, phenylalanine, proline and valine were resolved on capillary columns coated with either poly(trifluoropropylmethylsiloxane) or poly(propylene glycol) operated isothermally at 140 or 180°C. In the same year, Pollock reported the resolution of the *N*-TFA 2-butyl esters of 13 amino acids but those of aspartic acid, serine and threonine were only partially resolved. A study by Westley (1968) concluded that the resolution was directly proportional to the size of the groups attached to the alcoholic asymmetric carbon and to the proximity of the branching to the asymmetric centre. Thus 3,3-dimethyl-2-butanol gave superior resolution. In 1968, Pollock extended his study to the resolution of all the proteic amino acids except arginine, histidine and cystine. Three years later, 37 amino acid diastereomers were resolved as the *N*-TFA 2-butyl esters.

In 1977, König separated the *N*-pentafluoropropionyl (PFP) (+)-3-methyl-2-butyl esters of all the

Figure 4 Resolution of diastereomers of *N*-trifluoroacetyl amino acid (*N*-TFA) 2-octyl esters. (Reproduced with permission from Gil-Av E, Charles R and Fischer G (1965) Resolution of amino acids by gas chromatography. *Journal of Chromatography* 17: 408–410.)

common proteic amino acids, including arginine, histidine and tryptophan. Excellent resolution was obtained using a 25 m column coated with SE30 and temperature programming from 85 to 220°C at 2°C min⁻¹.

Optically Active Acylation Reagents

A variety of carbonyl chlorides have been used to generate optically active dipeptides. *N*-TFA-L(-)-prolyl chloride was first used in 1965 by Halpern and Westley who separated the isomers of alanine, leucine, methionine, phenylalanine, proline and valine. The reagent was chosen because it was thought that the cyclic nature of the derivative would preclude racemization via an oxazolinone mechanism. This reasoning was later shown by Bonner to be incorrect but the problem was overcome by modifying the derivatization procedure. The reagent subsequently came into fairly common use. It was extensively studied by Iwase and Murai who combined TFA, PFP and HFB forms with methyl, *n*-propyl, *n*-butyl, *tert*-butyl and cyclopentyl esters. By assessing the resolution of alanine, valine, leucine and isoleucine, they concluded that the esters of *n*-alkyl alcohols gave better resolution than branched or cyclic chain alcohols.

König introduced a second asymmetric centre into amino acid methyl esters using the chiral reagent L- α -chloroisovaleryl chloride. Formation of the 3-methyl-2-butyl esters enabled resolution of all the proteic amino acid diastereomers, including arginine, on an SE-30 capillary column in less than 1 h. A separate analysis was required for the basic amino acids. Nevertheless, the diastereomer approach was to be overtaken by the more direct and absolute method of enantiomer resolution on chiral phases.

Resolution of Enantiomers on Optically Active Columns

In 1966, Gil-Av demonstrated the first resolution of amino acid enantiomers on an optically active stationary phase. The *N*-TFA-2-butyl esters of alanine, valine and leucine were resolved on an *N*-TFA-L-isoleucine lauryl ester phase coated on a capillary column. However, phases of this type quickly gave way to dipeptide phases such as *N*-acyl-L,L-dipeptide alkyl esters which were first introduced by Feibush and Gil-Av in 1967 and which produced better resolution.

In 1970 Nakaparskin and colleagues separated 17 amino acid enantiomers on an *N*-TFA-L-val-L-val-cyclohexyl ester phase (val-val). In earlier studies, stainless-steel columns up to 500 ft long were used.

Consequently, analysis times were prolonged and the cystine, serine and threonine derivatives were degraded. In addition, dipeptide stationary phases such as val-val were functional over a limited temperature range or a limited maximum operating temperature. Columns were usually operated in isothermal mode.

König addressed the problem of temperature stability by introducing the *N*-TFA-L-phenylalanyl-L-leucine cyclohexyl ester which could be operated at 140°C. A later modification, the *N*-TFA-L-phenylalanyl-L-aspartic acid *bis*-(cyclohexyl) ester, was stable over the range 96–165°C and allowed the use of temperature programming. In addition, the introduction of glass capillary columns reduced degradation of the amino acid derivatives. The high boiling *N*-PFP isopropyl esters of aspartic acid, methionine, phenylalanine, glutamic acid, tyrosine, ornithine and lysine were eluted using a 20 m column. However, the diamide phases still left room for improvement in thermal stability and in peak resolution.

Another generation of phases was introduced by Frank, Nicholson and Bayer who linked the diamide moiety, L-valine *tert*-butylamide, to a polysiloxane backbone. Later termed Chirasil Val®, phases of this general type became predominant and are still in use. Early versions of this phase resulted in the overlap of D- and L-proline, D-isoleucine and L-*allo*-isoleucine, and L-threonine and D-*allo*-isoleucine. Nevertheless, the enantiomers of all the other proteic amino acids were resolved as the *N*-PFP *n*- or isopropyl esters in about 30 min by temperature programming from 90 to 190°C (Figure 5). Acid treatment of the glass capillary followed by methanol washing was necessary rigorously to exclude basic sites and thus to obtain satisfactory elution of cysteine, serine, threonine and tyrosine and to obtain a sharp peak for arginine. The relative retention times of the amino acids can be manipulated by including polar modifiers such as cyanopropyl and phenyl groups but the effect varies with specific amino acids. The L-valine *tert*-butyl moiety was subsequently grafted to chloropropionyl-methyl phenylmethyl silicone, a modified OV-225, and to Silar 10C, but no overall improvement was achieved.

Chirasil-Val® was further improved by the incorporation of 15% phenyl groups substituted for methyl groups in the dimethylsiloxane units and the introduction of fused silica capillary columns. Thermal stability, ease of handling and separation efficiency were improved. The product is commercially marketed as Heliflex™ Chirasil-Val®.

Later improvements included the enhancement of enantioselectivity and thermal stability by immobilization of the Chirasil-Val® by radical or thermal

Figure 5 Resolution of a racemic mixture of proteic amino acids as the *N*-(*O*, *S*)-pentafluoropropionyl *n*-propyl esters. (Reproduced with permission from Bayer E, Nicholson G and Frank H (1987) Separation of amino acid enantiomers using chiral polysiloxanes: quantitative analysis by enantiomer labeling. In Gehrke CC, Kuo KCT and Zumwalt RW (eds) *Amino Acid Analysis by Gas Chromatography*, Volume II, pp. 35–53. Boca Raton, FL: CRC Press.)

reactions. Chiral polysiloxanes with regular repeat units, e.g. trifluoroethyl ester-functionalized polysiloxanes supporting *L*-val-*tert*-butylamide or *L*- α -naphthylethylamine liquid phases, have shown improved enantioselectivity. Backbone modification achieved by replacing one methyl group per dialkylsiloxane unit with a pentyl or hexyl group improved resolution of arginine and tryptophan *N*-TFA *n*-propyl esters but the overall separation of the other amino acids was not significantly affected. However, satisfactory results have been obtained by varying the proportion of *L*-val-*tert*-butylamide on the polysiloxane backbone. A ratio of about 6–7 dimethylsiloxane units per chirally modified dialkyl siloxane unit is effective for the complete resolution of all components present in a chiral mixture of the 20 proteic amino acids in about 35 min on a 20 m \times 0.3 mm glass capillary column.

Most studies on amino acid enantiomer resolution on Chirasil-Val® type columns have used *N*-perfluoroacyl alkyl ester derivatives. However, other derivatives may present advantages in specific contexts. For example, the *N*-alkyloxycarbonyl alkylamide derivatives of proline are completely resolved on a Chirasil-Val® column. Similarly, König demonstrated the utility of isocyanate derivatives for resolving the enantiomers of *N*-methyl and β -hydroxy amino acids.

A radically different approach to enantiomer resolution has become possible with the development of cyclodextrins as stationary phases. Although suitable for liquid chromatography, the high melting point of cyclodextrins rendered them unsuitable for GC without further modification. König reduced the melting point and increased stability by introducing hydrophobic moieties by both partial and complete alkylation and acylation of the hydroxy groups. γ -Cyclodextrin substituted with 3-*O*-butyl and 2,6-di-*O*-pentyl residues was found to resolve most of the common amino acid enantiomers as the *N*-TFA methyl esters. Histidine enantiomers were only partially separated and arginine did not elute from the column. However, proline, 3,4-dihydroxyproline and pipecolic acid enantiomers were resolved, strongly suggesting that hydrogen bonding is not involved in the separatory mechanism. Atypical amino acids such as *N*-methyl and β -amino acids were also resolved.

More recently (1994), Abe explored capillary columns coated with four types of cyclodextrin derivatives of 6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-acetyl or *n*-butyl- β - and γ -cyclodextrin. Depending on the phase, all proteic amino acid enantiomers except for those of tryptophan were resolved as the *N*-TFA isopropyl esters. Variants such as 2,6-di-*O*-pentyl-3-*O*-propionyl- γ -cyclodextrin have also been used to

separate a number of amino acid enantiomers. Molecular modelling has positively correlated the GC elution order of proline derivatives on 2,6-di-*O*-methyl-3-*O*-trifluoroacetyl- β -cyclodextrin with the energies of the host-guest complexes.

Several satisfactory methods now exist for the resolution of amino acid enantiomers. Typically, 0.1% of a minor enantiomer can be precisely determined and, depending on the context and the specific method used, it is possible to assay as little as 0.01% or less.

Detectors

By far the majority of GC amino acid analyses have been conducted using flame ionization detectors (FID). These have the advantage of being sensitive and economical, but are nonspecific and provide no structural information.

Selective detectors confer distinct analytical advantages but are most often used to address special, nonroutine analytical problems. For example, the ability to detect a specific atom or molecular property can simplify sample preparation. Thus, by using a nitrogen/phosphorus-selective detector, contaminating compounds not containing nitrogen or phosphorus are simply not detected in most samples. Furthermore, it can reasonably be assumed that those peaks which have been detected contain nitrogen. In addition, problems caused by overlapping peaks are reduced. Selective detectors can also provide additional sensitivity. The ultimate detector is a mass spectrometer which can, depending on the context,

provide all of these advantages and also provide detailed structural information.

A number of selective detectors have been used to assay amino acids. Their use will be illustrated using some examples.

A nitrogen/phosphorus-specific detector, operated in the nitrogen mode, has been used to assay free amino acids in conifer tissues. All the proteic amino acids and several biologically important nonproteic amino acids were assayed at the low picomole level as the *N*-HFB isobutyl esters. Comparison of the FID chromatogram with the NPD chromatogram enabled identification of those compounds which did not contain nitrogen (Figure 6). Similarly, 1-aminocyclopropane-1-carboxylic acid, a precursor of the plant hormone ethylene, has been assayed as the *N*-benzoyl *n*-propyl derivative in the leaves and xylem sap of tomato plants. More recently (1997), 21 proteic and 33 nonproteic amino acids have been resolved in less than 30 min as the *N*-isobutoxycarbonyl methyl esters at a detection limit of 6–150 pg per injection. Small urine samples were analysed without prior clean-up and with no detectable influence from any non-nitrogen-containing compounds present.

Flame photometric detection (FPD) is useful for analysing sulphur-containing amino acids but has rarely been used in that context. Amino acid phosphorylation is an important biochemical regulatory mechanism and is also important for correlating protein structure and function. The *O*-phosphoamino acids, specifically *O*-phospho serine, threonine and tyrosine, have been assayed as the *N*-isobutoxycarbonyl methyl esters using FPD. The detection limits

Figure 6 Resolution of White Spruce leaf-free amino acids as the *N*-(*O*, *S*)-heptafluorobutyl isobutyl esters using a flame ionization detector. Peaks marked by asterisks were shown not to contain nitrogen by comparison with an analysis of the same sample using a nitrogen-selective detector. (Reproduced with permission from MacKenzie SL (1986) Amino acid analysis by gas-liquid chromatography using a nitrogen-selective detector. *Journal of Chromatography* 358: 219–230.)

ranged from 0.18 to 0.3 pmol, reflecting a sensitivity about 200 times greater than FID detection. The method has been applied to the determination of O-phosphoamino acids phosphorylated by protein kinase both *in vitro* and *in vivo* without radiolabelling. Other amino acids did not interfere. The secondary amino acids, proline, pipercolic, thioproline, hydroxyproline and hydroxypipercolic acids, have also been assayed using FPD. Detection limits for the N-dimethylthiophosphoryl methyl esters were 0.1–0.7 pmol per injection.

Electron capture detectors are particularly useful for detection of the strongly electronegative perfluoroacyl derivatives of amino acids, but few studies have been conducted. Typically, as little as 1.4 pmol of tyrosine has been detected in a standard amino acid mixture. γ -Aminobutyric acid and five other aliphatic acids have been assayed in small volumes of supernatants from brain homogenates following sequential reaction with isobutyl chloroformate and pentafluorophenol.

Mass spectrometric detection provides structural as well as quantitative information. It is most frequently used either to confirm the structure of derivatives during the development of new protocols or to identify unknown compounds. Detection limits are frequently in the femtomole range. Electron impact (EI) ionization is most commonly used but both positive and negative ion chemical ionization have also been applied. Selected ion monitoring (SIM) of diagnostic ions is often used to increase sensitivity.

Typical examples of the structural information role of a mass spectrometric detector are the identification of O-phosphoamino acids in urine hydrolysates, the identification of amino acid ethyl esters in wines, the determination of amino acid composition in small peptides, and the assaying of γ -aminobutyric acid in mouse brain synaptosomes following therapy with the antiepileptic drug valproic acid. The versatility of GC-mass spectrometry (GC-MS) is further illustrated by the identification of 3-OH-4-methyldecanoic acid, a fungal cyclodepsipeptide, and by the simultaneous analysis of branched-chain carboxylic, α -oxo, α -hydroxy and α -amino acids in the urine of patients suffering from maple syrup urine disease. GC-MS has also been used to characterize binding media from medieval polychrome sculptures. Animal glues, casein, egg and drying oils were identified as components of the binders of paint and ground layers.

The expense of mass spectrometers mitigates against their use as routine analytical detectors and many real sample analyses by GC-MS (as distinct from the analysis of standard mixtures) have been directed to addressing analytical problems which cannot be resolved using other types of detectors.

The ratios of the stable isotopes of C and N are used in the assessment of *in vivo* protein turnover studies, and in identifying the sources and history of organic matter. Both natural abundances and the ratios obtained after enrichment with singly or multiply labelled amino acids or other compounds such as ^{13}C -glucose, pyruvate or acetate have been determined. The ratios may be determined after online combustion following GC and introduction of the resultant gases into a conventional isotope ratio mass spectrometer. This approach has been used to study ^{15}N : ^{14}N isotopic ratios in plasma-free amino acids and, by eliminating many preparative steps, requires only about 500 μL -of plasma, whereas preparatory methods may require as much as 60 mL.

Alternatively, the intact labelled compounds can be introduced directly into the mass spectrometer. For example, by combining stable isotope dilution with the use of EI and SIM to monitor the $[\text{M}-57]^+$ peak, homocysteine sulfinic acid, homocysteic acid, cystine sulfinic acid and cysteic acid have been shown to be agonistic to N-methyl-D-aspartate receptors in brain tissue. This approach also enabled the identification and quantitation of these compounds in normal human serum. Similarly, endogenous and newly synthesized concentrations of the neurotransmitter amino acids γ -aminobutyric acid, glutamate and aspartate have been assayed in brain slices following incubation with ^{13}C -labelled precursors.

Future Developments

The techniques for derivatizing and separating the standard amino acids in protein hydrolysates are mature and there is no significant room for improvement. Given the existence of quantitative derivatization protocols which proceed very rapidly, it is doubtful whether the development of on-column derivatization would constitute a significant advantage. Similarly, proteic amino acids can now be assayed in less than 10 min, so, given the availability of reliable automatic injectors, a reduction in analysis time is not of significant value.

Physiological samples may contain several hundred amino acids and these cannot, at present, all be resolved on any one single column. Frequently, however, only a subset is of interest. Thus, although the simultaneous derivatization and separation of all the proteic amino acids and as many as 50 of the more common nonproteic amino acids are now possible, it is likely that procedures targeted at specific subsets will remain important in specific contexts. The sensitivity of the FID detector is adequate for most analytical purposes but mass spectrometric detectors

will remain important for specialized applications requiring femtomole sensitivity.

The first approach to the automatic liquid chromatography (LC) of amino acids (AAs) – known today as ion exchange chromatography (IEC) – was published by Spackman *et al.* in 1958. In over 40 years later, it now takes less than 5 min (**Figure 1**) to separate and quantitate the essential protein AAs instead of 2 days. Early separations were carried out by post-column derivatization.

Over the last 20 years LC has offered unlimited possibilities in both the preparative and analytical scale. The wide choice and sophisticated columns, detectors, derivatization procedures, development of modern instrumentation and data-handling systems reduce time and costs, and give versatility and automation in Good Laboratory Practice (GLP)- controlled conditions for selectivity, sensitivity and reproducibility. It is the responsibility of the researcher to choose the most appropriate method for the given task. The most popular LC method for analysis of both free AAs (present in many natural matrices, biological fluids and tissues, feed and foodstuffs) and of those constituents of protein hydrolysates is now reversed-phase (RP) chromatography after pre-column derivatization of the AAs.

Numerous methods for derivatization are available in the literature. This article will discuss the advantages and drawbacks of the commonly used derivatives.

Current trends in AA analysis identify the best conditions for enantiomer separation and the development of LC-mass spectrometry (LC-MS).

LC of Underivatized AAs

To attain one of the main advantages of LC – separating the ‘classical 20’ as underivatized AAs – has appealed to chromatographers. In spite of a number of efforts, the simultaneous LC of underivatized AAs has remained of secondary importance. Determination of a few selected AAs, such as tryptophan or sulfur-containing AAs, has proved to be fruitful for special tasks.

The aim of various investigations was to render unnecessary the time-consuming derivatization techniques. However, the characteristics of the free AAs are considerably different from each other and their various structural properties did not permit their easy resolution. Thus, in attempting to achieve better separation of free AAs, further means of discrimination were needed. For this purpose special techniques have been introduced, such as the use of various phase systems, ion pair and ligand exchange chromatography, column-switching techniques or anion exchange chromatography with electrochemical detection.

The solvent-generated ion exchange phase system ensured the gradient elution of 19 AAs (**Figure 2A**): some, but not all, are baseline-separated. A simple isocratic method using aqueous, copper acetate/alkyl-sulfonate additives containing acetate buffer (pH 5.6) as mobile phase, a conventional RP column and UV detection (230–240 nm) at different temperatures and varying the concentrations of additives was unable to separate the classical 20 protein amino acids. Significant improvement in the separation can be obtained by column switching (**Figure 2B**), as well as by using an anion exchange column, a quaternary

Figure 1 Separation of the phenylthiocarbamyl AAs separated on TSKgel Super-ODS (for details see Table 3). Peaks: 1, ASP; 2, Glu; 3, Ser; 4, Gly; 5, His; 6, Arg; 7, Thr; 8, Ala; 9, Pro; 10, NH_4^+ ; 11, Tyr; 12, Val; 13, Met; 14, Cys; 15, Ile; 16, Leu; 17, Phe; 18, Lys. (Reproduced with permission from Tosohaas, *The Bioseparation Specialist*, (1995) Catalogue p. 157, Figure 9/2.)

gradient mobile phase and pulsed amperometric detection (Figure 2C). For tryptophan and the sulfur-containing AAs (cysteine/cystine, methionine, glutathione, etc.), the fast isocratic elution of the underivatized samples has gained wide acceptance and is a powerful tool in their quantitation.

Tryptophan can be measured directly, within 8 min, in neutralized alkaline hydrolysates of feed and foodstuffs, using an RP column, 5% methanol containing acetate buffer (pH \sim 4.0) and UV detection at 280 nm. The pulsed amperometric detection of sulfur-containing AAs, at the low pmol level, was carried out with an Au working- and an Ag/AgCl reference electrode, subsequent to their separation on both cation exchange and on RP columns, applying as mobile phase $0.1 \text{ mol L}^{-1} \text{ HClO}_4/0.15 \text{ mol L}^{-1} \text{ NaClO}_4/5\% \text{ ACN}$.

LC of Derivatized AAs

Derivatization studies have concerned the optimization of parameters, such as the yield and stability of derivatives, to separate and quantitate all AAs with a simple and fast elution procedure.

Post-column Derivatization (Table 1, Figure 3)

Post-column derivatization was the first development of IEC in the area of RP/high performance liquid chromatography (HPLC), in its pioneer period. It took time to develop pre-column derivatization concepts which resulted in considerable advantages.

Drawbacks of the post-column techniques (Table 1) are long elution times and the need for costly devices, such as a delivery system for the derivatizing reagent (one or more extra pumps); (a) mixing chamber for the column effluent and the re-

agent(s); special thermostable reactors (packed bed, air-segmented and/or coil reactors) ensuring the necessary delay for quantitative reactions accompanied with as small band broadening as possible. Last but not least, the mobile phase was probably incompatible with the derivatizing reagent. The preferred mobile phase might be inappropriate for the optimum conditions of derivatization reaction. The early and current stages of post-column methods can be illustrated by elution followed by post-column reaction with ninhydrin (NH₂YD; Figure 3A), with *o*-phthaldialdehyde/ β -mercaptoethanol (OPA/MCE; Figure 3B), or with 1,2-naphthoquinone-4-sulfonyl chloride (NQS; Figure 3C). All three types of derivatives have been separated in most cases on ion exchange resin columns from the early 1970s. Recent post-column methods are without exception, slow separations (Table 1). However, the efficiency of the recently published methods of NH₂YD derivatives using short columns is superior, determining 59 compounds in 150 min and 40 compounds in 120 min respectively.

Pre-column Derivatization (Tables 2 and 3; Figures 4–6)

Pre-column derivatization offers numerous advantages. It requires less equipment and allows the evaluation of the derivatives in an easier way from the point of view of their selectivity, sensitivity, various means of detection, derivatization yield, stability and storability. All of these phenomena can be controlled and improved by use of modern instrumental techniques and computerization, both individually and simultaneously. Potential disadvantages in pre-column derivatization as procedures can be completely avoided: contamination from the reagents (due to their insufficient purity) and loss of analyte

from incomplete interaction, undesirable side reactions and sample handling losses.

Although numerous pre-column derivatization techniques have been introduced in the last 30 years, none complies with the criteria of an ideal procedure: providing rapid and quantitative interaction in aqueous media, permitting mild conditions, ensuring interaction with both primary and secondary AAs and resulting in single and stable derivatives in the case of all AAs.

OPA Derivatives (Table 2 and Figure 4)

The pioneering work of Roth (1971) on the very fast reaction of AAs in aqueous solutions with ophthalaldehyde mercaptoethanol (OPA/MCE), detectable by

both UV and fluorescence, without the need to remove excess reagent, represented a great advance. Because of the different stability of the isoindoles obtained from the reaction of AAs with OPA/MCE, pre-column derivatization with 3-mercaptopropionic acid (MPA) and several *N*-alkyl-L/D-cysteines was proposed. The OPA/MPA and OPA/*N*-acetyl-L-cysteine (NAC) reagents provide more stable isoindoles compared to those formed with OPA/MCE, and the optical resolution of enantiomeric amino acids with OPA/NAC, as well as with other *N*-alkyl-L/D-cysteine reagents, has opened a new area in enantiomer separation of AAs. Due to robotic autosamplers which provide excellent reproducibility for even moderately quantitative interactions, most AA analyses are

performed with OPA derivatives. The essential shortage of an OPA/S_H-group reagent (reactive toward the primary AAs only) was eliminated by Shuster's principle – the automatic two-step pre-column derivatization method applying the OPA/MPA/fluorenylmethyl chloroformate (FMOC) reagent, which also ensures derivatization of the secondary AAs. A high speed elution of OPA/MPA/FMOC derivatives was shown recently (Table 2, Figure 4: 19 compounds/8 min). Evaluating the improvements between the corresponding early and recent procedures, in the newer methods shorter, thermostated columns of smaller particle size with autosamplers are now used, giving greater sensitivity and reproducibility.

Phenylthiocarbamyl (PTC), FMOC, 1-*N,N'*-Dimethylaminonaphthalene-5-sulfonyl (DANS) and Dimethylaminoazobenzenesulfonyl (DABS) Derivatives (Table 3, Figures 1, 5 and 6)

Judging by the number of publications in the last decade, the interest in the PTC and FMOC deriva-

tives has proved to be lasting, while the application of DANS and DABS derivatives is decreasing. However, in the direct enantiomer separation of AAs, the use of DANS derivatives is preferred.

The reaction of AAs with *phenylisothiocyanate* (Table 3, Figures 1 and 5), in water-free media at ambient temperature is quantitative and fast (10 min), resulting in the highly stable single PTC derivatives (except for cyst(e)ines in hydrolysates which elute in one to four peaks). The excess reagent is removed by vacuum, and the PTC derivatives can be stored in the freezer for an unlimited time, and for a day after dissolution in buffer at 4°C. UV detection at 254 nm allows their quantitation in the low pmol range. The short PicoTag and the short TSK gel columns can separate 17 AAs within 12 min and 4.5 min, respectively.

The first LC separation of the strongly fluorescent DANS AAs has been used earlier in protein chemistry and in thin-layer chromatography. The decreased popularity of this technique in LC can be

explained by its two main disadvantages: long reaction times, or elevated temperatures for derivatization, and generation of fluorescent side products (DANS hydroxide, DANS amide) and interference from excess reagent. The disturbing effect of these compounds cannot be completely eliminated and they elute between the AA derivatives. No significant improvement has been obtained and cannot be expected.

DABS AAs were first separated applying pre-column labelling. Derivatization was performed in $\text{Na}_2\text{CO}_3/\text{NaHCO}_3$ buffer, at pH \sim 8.9 with DABS chloride dissolved in acetone under continuous stirring at 80°C for 10 min. DABS AAs can be

stored for 4 weeks in solution at 25°C, without any changes. In spite of the unique stability of DABS AAs in aqueous media, and the improvement in their chromatographic conditions, the use of DABS AAs is dwindling.

FMOC was introduced in 1983, as a fluorescent labelling agent, reacting rapidly with both primary and secondary AAs, under mild conditions (borate buffer, pH 7.7–8.0) to give stable derivatives. The excess reagent is extracted by pentane. Recent derivatization studies have shown that, depending on the time (2 and 40 min) and pH (8.0 and 11.4), considerable differences can be found. At pH \sim 8, acidic AAs manifest low responses, and slow reaction

is experienced; histidine and tyrosine give their mono- and disubstituted derivatives in varying ratios. With longer reaction times, the amount of disubstituted histidine decreases and that of tyrosine increases, together with interfering hydrolysis products of the reagent. At pH ~ 11.4 faster reaction and less interfering hydrolysis products are found. After 40 min reaction time, the monosubstituted histidine and the disubstituted tyrosine are formed in quantitative yield. Also 30% less hydrolysis product is obtained, favouring the resolution of the neighbouring alanine. The separation of the FMOC derivatives and

the presence of interfering substances are shown in Figure 6.

Chiral Separations (Table 4 and Figure 7)

The knowledge of the distribution of AA enantiomers in different matrices, and/or the enantiomeric purity of AAs, is of primary importance in the quality control of peptide syntheses for pharmaceuticals/medicines, as well as in various plant products and in high AA-containing foods, including baby formulas.

For separation and quantitation of enantiomers, HPLC is the method of choice. The application of the three main approaches for enantiomer separation is shown in Table 4 and Figure 7, including direct, chiral mobile-phase additive (CMA) and chiral stationary phase (CSP) and indirect methods (chiral derivatization reagent CDR).

Direct Methods

Applying either γ -cyclodextrin (γ -CD) or Cu(II) salts together with N^2 - S -(N^2 - R -)2'-hydroxypropyl- S -

phenylalanineamide as CMA is very time-consuming (Figure 7A): the separation of three AA pairs requires more than 2 h. Thus, CMAs can be regarded as an inferior approach in the chiral recognition of AA enantiomers, due to the need for a continuous supply of the often expensive CMA and to the disadvantageous chromatographic conditions. Bonded N^2 - S -(N^2 - R -)2'-hydroxypropyl- S -phenylalanine-amide, CSP, allows the comparison of the CMA and CSP protocols for the same enantiomer separations. The CSP method resolved four pairs of

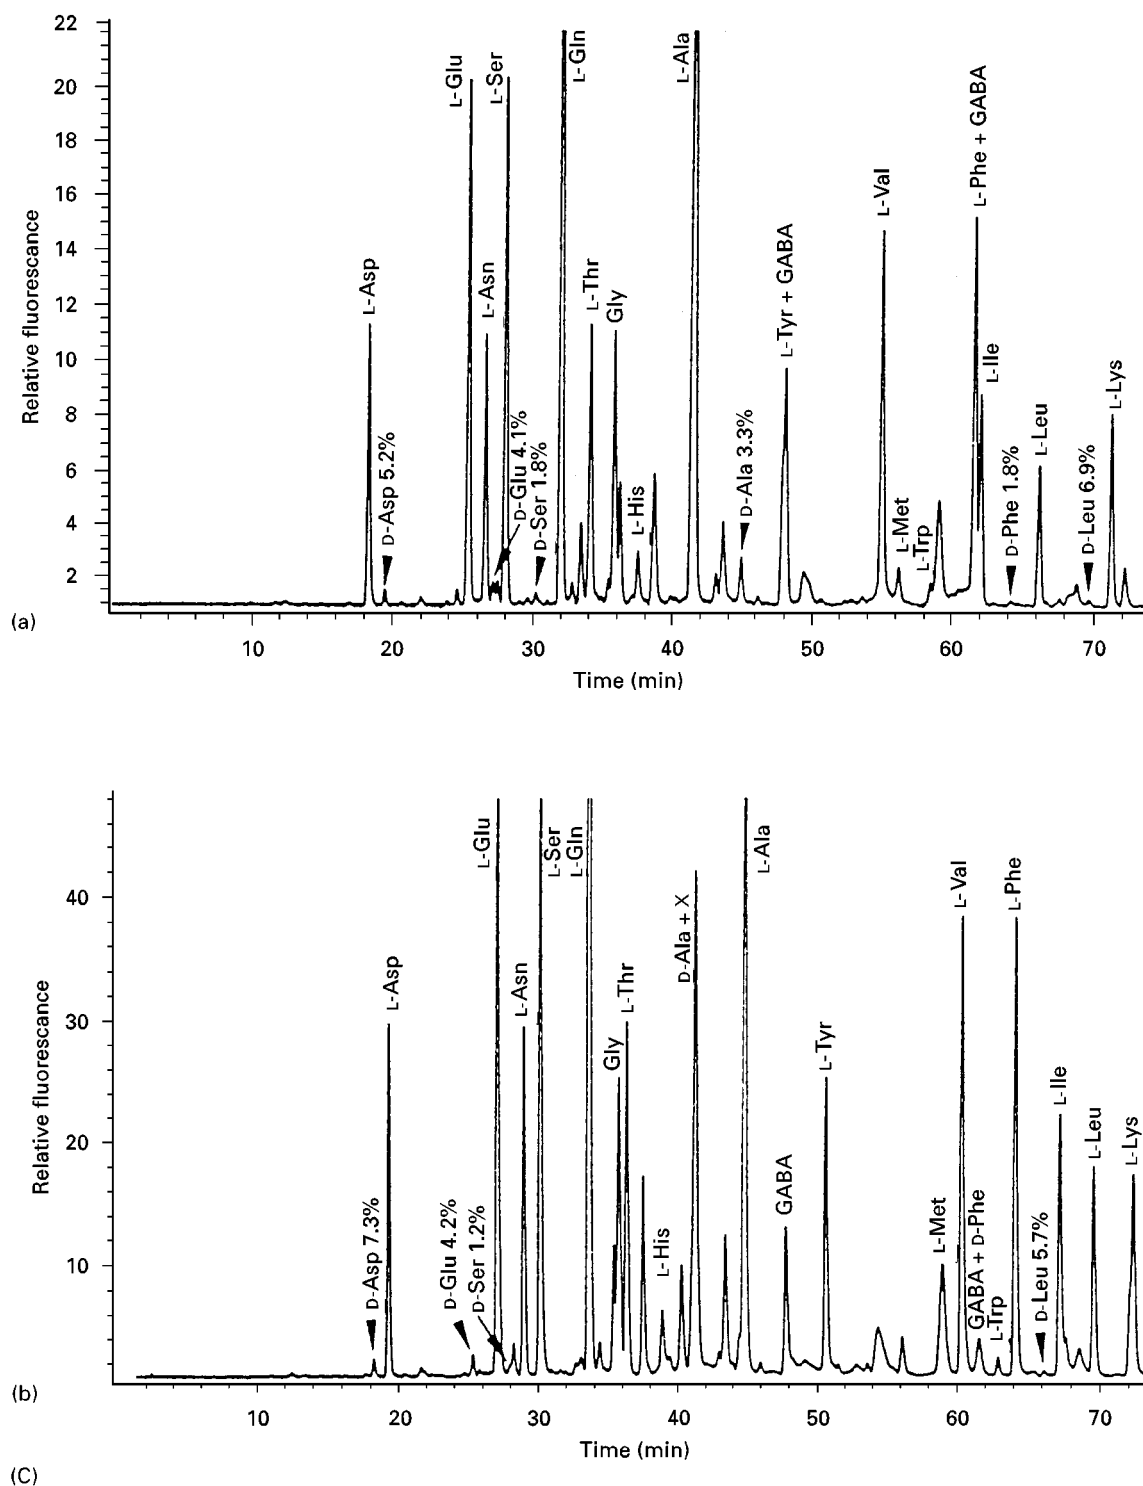

Figure 7 Continued

dansylated AAs within 30 min, attesting to the superiority of CSP over CMA. Recently, the elution of the PTC AAs on a new CSP (Figure 7B) permitted the partial separation of 18 AA pairs within 150 min.

Indirect Methods

Spectacular results have been achieved with the separation of AAs derivatized by CDRs (Figure 7C). Performing the separation with both OPA/N-L(D)-

acetyl-cysteinyl and with OPA/N-L(D)-isobutyrylcysteinyl AA derivatives gave excellent resolution of enantiomers. Consequently, the CDR technique is the primary importance in a number of practical applications of the separation of enantiomeric AAs. The interaction of AAs with the enantiomerically pure reagents takes place at ambient temperature, without racemization, resulting in the formation of stable diastereomer derivatives.

Online LC-MS

In the case of AAs, thermospray ionization has been displaced by the milder techniques of electrospray (ES) and atmospheric pressure chemical ionization (APCI), converting analyte molecules without fragmentation into ions. The analyte should contain the AAs in a stable form: either in the free condition or in the form of stable derivatives, such as phenylthiohydantoin (PTH) or PTCs. Significantly reduced flow rates are essential ($100\text{--}300\text{ nL min}^{-1}$) for stable ES and APCI operation. In automated Edman microsequencing, the ES-MS of PTH derivatives. The protonated molecules were measured with a linear response in the $50\text{--}1000\text{ fmol}$ level.

Future Trends

Efforts are needed to extend the life time, plate number and reproducibility of columns, and to standardize testing methods. The extended use of thermostated columns is desirable in order to obtain reproducibility in absolute and relative retention times. LC-MS will be more widely used in laboratories as the cost of these instruments falls to the level of GC-MS, and/or an all-purpose interface becomes available.

Introduction

Thin-layer chromatography (TLC) is a simple and inexpensive technique permitting a number of samples to be handled simultaneously, thus yielding a higher precision than sequential analysis. The inert character of the thin-layer material makes it ideally

suitable for use with strong corrosive reagents and one can perform many kinds of chemical reactions on the plate, both from the points of view of detecting and locating the spot and of achieving improved separation. Certain groups of interest can be chemically bonded to the reactive groups of support material, e.g. silanization for reversed-phase studies. Impregnation of the adsorbent with a variety of reagents adds an additional feature for influencing the adsorption characteristics without covalently affecting the inert character of the adsorbent. TLC is also successful in providing direct resolution of enantiomers of a variety of compounds by the proper manipulation of the support material. The analysis of amino

acids and derivatives and the resolution of enantiomers of amino acids by TLC techniques using a wide variety of adsorbents and impregnating agents, the possibility of obtaining relationships between the chromatographic behaviour and chemical structure and the many practical applications drawn from the literature are described in detail in the following sections.

Adsorbents and Thin Layers

A variety of adsorbents such as silica gel, alumina, polyamide and cellulose are available commercially and are used to make thin layers for TLC. Alumina and silica gel are used with or without a suitable binder such as gypsum or starch. Mixtures of two adsorbents or adsorbents impregnated with certain reagents such as 8-hydroxyquinoline or different metal ions have also been used successfully to improve resolution.

Cellulose layers have several advantages: they are stable, they can be used with various specific reagents and they give reproducible data. They are particularly recommended for quantitative evaluation by densitometry. The drawbacks of cellulose layers are that corrosive reagents cannot be used and the sensitivities of detection reactions of certain amino acids are lower than on silica gel layers.

The best known and most widely used adsorbents for TLC purposes are from Merck, but other products can be used satisfactorily. Pre-coated plates are widely available and increasingly used for the investigation of amino acids and their derivatives. For example, ready-made cellulose layers from Macherey-Nagel (Germany) containing MN cellulose-300 in appropriately bound form are one of the best-known products. Chiralplate from the same firm and Chir from Merck, for the separation of enantiomers of amino acids and their various derivatives, contain a coating of reversed-phase silica gel impregnated with a chiral selector and copper ions. Using home-made thin-layer plates is possible and it is recommended that one should not change the brand of adsorbent during a particular set of experiments.

Application of mixed layers of cellulose and the ion exchanger Amberlite CG-120 and a double layer consisting of a 2 cm band of cellulose + cation exchanger (45 + 5 g) in aqueous CM-cellulose (0.05%), with the remaining portion of the layer prepared from cellulose SF suspension, have also been effectively used. A newly synthesized support named aminoplast comparable with that of starch and cellulose has been reported. Nevertheless, silica gel continues to be the most widely used and successful material.

Preparation of Thin-layer Plates

Most thin-layer work is done on layers prepared from water-based slurries of the adsorbents. Even with the same amount and type of binder, the amount of water used for a given slurry varies with kinds and brands of adsorbents. For example, in the case of cellulose the amount of powder to be mixed with water varies depending on the supplier: Serva, Camag and Whatman recommend the use of 60–80 mL, 65 mL and 25 mL water for 10 g of their cellulose powders, respectively. These slurries may be prepared by shaking a stoppered flask or by homogenizing for a few seconds with a mechanical mixer. On the other hand, for the preparation of an aluminium oxide slurry (acidic, basic or neutral), it is recommended that 35 g of aluminium oxide is used with 40 mL water for spreading equipment, and 6 g of adsorbent in 15 mL ethanol–water (9:1) mixture for pouring directly on to the plate without a spreading apparatus. A slurry of 120 g of alumina G in 110 mL of water has been used successfully to make 1 mm-thick layers for preparative TLC. In general, cellulose powders contain impurities that are soluble in water or organic solvents, and these should be removed by washing the cellulose several times with acetic acid (0.1 mol L^{-1}), methanol and acetone and drying before use. The layer is made by turbo-mixing MN (Machery-Nagel) cellulose 300 (15 g) for 10 min in distilled water (90 mL) and then spreading it to give a 0.25 mm thick layer. The layers are left overnight to dry.

A slurry of silica gel G (50 g) in distilled water (100 mL) is prepared and spread with the help of a Stahl-type applicator on five glass plates of $20 \times 20 \text{ cm}$ to obtain 0.5 mm thick layers. The plates are allowed to set properly at room temperature and then dried (activated) in an oven at an appropriate temperature ($60\text{--}90^\circ\text{C}$) for 6 h or overnight. The plates are cooled to room temperature before applying the samples.

The same method has been used successfully to prepare plates with silica gel, silica gel polyamide, cellulose and these adsorbents impregnated with a variety of reagents including di-(2-ethylhexyl) orthophosphoric acid (HDEHP), tri-octyl-phosphine oxide (TOPO), 8-hydroxyquinoline, dibenzoyl methane and several metal salts. Brucine and tartaric acid are also mixed in slurries of silica gel as impregnating reagents to resolve enantiomers of amino acids and their PTH derivatives. Mixtures of H_2O – EtOH and other organic solvents can also be used, depending on the nature of the impregnating reagents. Citrate and phosphate buffers have also been used for slurring silica gel in place of water. It is customary to use 0.25

or 0.50 mm thick layers in activated form, but for preparative purposes 1–2 mm layers are best.

Development of Chromatograms

Standard solutions of amino acids are prepared in a suitable solvent such as 70% EtOH or 0.1 mol L⁻¹ HCl in 95% ethanol. These solutions are generally applied as tight spots, 1–2 cm from the bottom of each layer, using a glass capillary or Hamilton syringe. In the beginning a higher concentration, e.g. 500 ng or more, is applied; however, the detection limits are determined for the system developed by repeating the experiment with lower concentrations.

The chromatograms are generally developed in rectangular glass chambers, which should be paper-lined for good chamber saturation and pre-equilibrated for 20–30 min with solvent before use. The time taken depends on several factors such as the nature of the adsorbent, the solvent system and the temperature. The developed chromatograms are dried in an oven between 60 and 100°C, and the cooled plates are usually sprayed with ninhydrin reagent. Heating at 90–100°C for 5–10 min produces blue to purple zones of all amino acids except proline (yellow spot).

The same method is adopted for both one- and two-dimensional modes. The locating reagent is used after the second run, and a more polar solvent is generally used to develop the chromatogram in the second dimension.

Separation of Amino Acids

Silica gel and cellulose are the commonest adsorbents for one- or two-dimensional resolution of amino acids. These have been used as such (untreated) or impregnated with some other reagent employing a large number of solvents. Some of the successful systems for one- and two-dimensional resolution of amino acids are given in Table 1 and Table 2. Table 3 shows a comparative account of the separation of amino acids (R_F values) on silica gel, cellulose and ion exchange thin layers using *n*-butanol–acetic acid–water (3 : 1 : 1). The data are of great value for separating and detecting amino acids by one-dimensional TLC and based on it the amino acids have been grouped for the separation of 18-component mixtures (separation I) and essential amino acid mixtures (separation II) by calculating

the resolution possibilities of each pair of acids (Table 4).

Amino acids chromatographed in the presence of trichloroacetic acid (used in deproteinizing serum samples) show anomalous behaviour, and this interference can be almost completely removed by predevelopment (twice) in ether saturated with formic acid. The migration sequences for the separation of 18 amino acids on reversed-phase thin layers including C₁₈ chemically bonded silica gel and on cellulose in *n*-propanol–H₂O (7 : 3, v/v) have generally

been found to be the same. Sorbents with ion exchange properties such as diethylaminoethyl (DEAE)–cellulose have also been used as the stationary phase for TLC separation of the main protein amino acids with *n*-butanol–acetic acid–water (5 : 1 : 6, upper phase) and pyridine–water (4 : 1) in one- and two-dimensional modes.

Locating the spots of amino acids After drying the chromatogram it may be viewed under ultraviolet light if the absorbent had a fluorescent indicator, or

the compounds – such as dansyl amino acids – fluoresce. Solvent fronts indicate regularity of solvent flow. Ninhydrin is the most commonly used reagent for the detection of amino acids, and a very large number of ninhydrin reagent compositions have been reported in the literature. The reagent may be made slightly acidic with a weak acid following the use of an alkaline solvent and vice versa. Constancy of colour formed may be attained by the addition of complex-forming cations (Cu^{2+} , Cd^{2+} or Ca^{2+}) and specific colours may be produced by the addition of bases such as collidine or benzylamine. Some of the ninhydrin compositions and their applications are described below.

1. A solution of ninhydrin (0.2% w/v in acetone) is prepared with the addition of a few drops of collidine or glacial acetic acid. The chromatogram is dipped or sprayed with the solution and dried at 60°C for about 20 min or at 100°C for 5–10 min. Excessive heating causes a dark background. Most amino acids give a violet colour, while aspartic acid gives bluish-red, and proline and hydroxyproline give a yellow colour; the sensitivity limit is 1 µg.
2. Ninhydrin (0.3 g) in *n*-butanol (100 mL) containing acetic acid (3 mL) is sprayed on a dried, solvent-free layer, which is then heated for 30 min at 60°C or for 10 min 110°C. Detection limits range from 0.001 µg for alanine to 0.1 µg for proline and aspartic acid.
3. Ninhydrin (0.3 g), glacial acetic acid (20 mL) and collidine (5 mL) are made up to 100 mL with ethanol or ninhydrin (0.1%, w/v) in acetone–glacial acetic acid–collidine (100 : 30 : 4%).
4. A solution of cadmium acetate (0.5 g) in water (50 mL) and glacial acetic acid (10 mL) is made up (500 mL) with acetone. Portions of this solution are taken and solid ninhydrin is added to give a final concentration of 0.2% w/v. The chromatogram is sprayed and heated at 60°C for 15 min. The results are noted immediately and again after 24 h, at room temperature. Alternatively, the layer is impregnated thoroughly with the reagent and the colours are allowed to develop in the dark at room temperature for 24 h. This reagent gives permanent colours, mainly red but yellow for proline. Sensitivity is 0.5 nmol.
5. Ninhydrin (1.0 g) in absolute ethanol (700 mL), 2,4,6-collidine (29 mL), and acetic acid (210 mL) has been used for spraying on solvent-free cellulose layers. The chromatogram is then dried for 20 min at 90°C.
6. Development of ion exchange resin layers in ninhydrin (1% w/v) in acetone containing collidine (10% w/v) at room temperature for 24 h, or at 70°C for 10 min has also been recommended.
7. Spray of ninhydrin (0.1% or 0.2% w/v in acetone on chromatograms followed by heating at 60 or 90°C for 10–20 min has also been used.
8. Polychromatic reagent consists of firstly, ninhydrin (0.2% w/v) in ethanol (50 mL) + acetic acid (10 mL) + 2,4,5-collidine (2 mL) and secondly, a solution of copper nitrate (1.0% w/v) in absolute ethanol. The two solutions are mixed in a ratio of 50 : 3 before use. Replacement of ethanol by methanol also gives polychromatic amino acid detection by joint application of ninhydrin and primary, secondary or tertiary amines. The layers are first sprayed with diethylamine, dried for 3 min at 110°C, cooled, and then sprayed with 0.2% w/v methanolic ninhydrin and heated for 10 min at 110°C, when the spots of amino acids appear on

a pale blue background. Use of ninhydrin (0.27 g), isatin (0.13 g), and triethylamine (2 mL) in methanol (100 mL) gives spots of amino acids on a yellow background.

Several other reactions have also been used for the detection of specific amino acids (Table 5). Oxalic acid (ethanolic 1.25% w/v), dithio-oxamide (ethanolic-saturated) and dithizone followed by ninhydrin have been used to aid identification and detection of amino acids with various specific colours. Acetylacetone-formaldehyde gives yellow spots under UV light. Using isatin-ninhydrin (5 : 2) in *n*-butanol or modifying ninhydrin detection reagent by addition of D-camphor, and various acids improves identification of amino acids. Spraying of layers with 1,3-indanedione or *o*-mercaptobenzoic acid prior to ninhydrin improves sensitivity limits and colour differentiation. 3,5-Dinitrobenzoyl chloride can be used to detect amino acids at a 3–4 µg level, and synchronization of timing is achieved by coupling pneumatic nebulization with optical fibre-based detection in a chemiluminescence TLC system to detect dansyl-amino acids. Chromatograms sprayed with ninhydrin (0.3 g ninhydrin in 100 mL *n*-butanol plus 3 mL of glacial acetic acid), air-dried for 5 s, resprayed and heated in an oven at 110°C for 10 min gives the best sensitivity, stability and colour differentiation compared with different recipes of ninhydrin and fluorescamine sprays.

Separation of Amino Acid Derivatives

Separation and identification of derivatives of amino acids such as dinitrophenyl (DNP), PTH, dansyl and dimethylamino azobenzene isothiocyanate (DABITC), is very important, particularly in the primary structure determination of peptides and proteins. The preparation of PTH, dansyl, and DNP amino acids, and the methods for their identification after separation from the *N*-terminal of peptides and proteins, are available in literature.

PTH Amino Acids

The PTH amino acids are sensitive to light, and optically active derivatives racemize easily. Both manual and automated, and liquid-phase and solid-phase Edman degradation methods (coupling of the NH₂ group of an amino acid at the *N*-terminal end of a polypeptide or a free molecule with phenyl isothiocyanate) are currently used for small and large polypeptides to establish their primary structure. An automated sequencer can deliver several PTH amino acids in 24 h and these are required to be identified rapidly to match the output.

Table 5 Detection reactions for specific amino acids

<i>Amino acid</i>	<i>Reagent</i>
Arg	8-Hydroxyquinoline
Arg	α -Naphthol, urea, Br ₂
Asp	Ninhydrin, borate solution, HCl
Cys, Met	NaN ₃ , iodine
Gly	<i>o</i> -Phthalaldehyde, KOH
His	Sulfanilic acid
Ser, Thr, Tyr	Sodium metaperiodate, Nessler reagent
Try	<i>p</i> -Dimethylaminobenzaldehyde

TLC has been used for the identification of PTH amino acids since Edman and Begg used it in their classical work describing the automatic sequencer. Various TLC systems with different kinds of adsorbents, such as alumina, silica gel and polyamide, have been reported. The results of some TLC systems used for resolution and identification of PTH amino acids are given below.

Two-dimensional TLC has been carried out using plates coated with polyamide containing three fluorescent additives when all PTH amino acids show coloured spots under UV light. About 0.1 nmol of PTH amino acid can be detected. Typical results are given in Table 6. A compilation of solvent mixtures useful in the TLC of PTH amino acids on various supports is given in Table 7.

Resolution and identification of PTH amino acids on silica or polyamide layers, as discussed above, do not discriminate between derivatives of Leu/Ile and cannot resolve complex mixtures without two-dimensional chromatography. Difficulties in resolving combinations of PTH Phe/Val/Met/Thr and PTH Asp and Glu are also observed. Use of chloroform-acetic acid (27 : 3, v/v) and chloroform-methanol (30 : 4, v/v) has been found to be extremely satisfactory for discriminating between PTH Asp and PTH Glu, as the difference in their *hR_F* values is around 10 units. The difficulties in resolving and identifying various combinations of PTH amino acids can be overcome by the use of certain solvent systems, given in Table 7.

Detection of PTH amino acids The methods of detection include firstly, spraying a dilute solution of fluorescein on a plain layer of silica gel when the spots are visible as dark areas against a yellow background in UV light; secondly, exposing the dried chromatograms to iodine vapours to locate the spots as light brown compact zones; and thirdly, use of iodine-azide solution when bleached spots on a light brown background are observed. The iodine azide method is considered less sensitive and causes difficulties in demarcating the exact spots and measuring the

plate with mixed fluorescent additives is used (Table 6). A rapid colour-coded system due to ninhydrin spray is mentioned in Table 8; the colours produced allow easy identification of those amino acids that have nearly identical R_F values, for example, Lys and Ser degradation products, Ala/Met/Phe, and Tyr/Thr. The method is significant because it gives positive identifications of PTH Ser/Lys/Glu/Asp and their respective amides, which cannot be identified by gas chromatography (GC).

Dansyl Amino Acids

Derivatization of free amino group of amino acids with 5-methylaminonaphthalene-1-sulfonyl (dansyl) chloride has become increasingly popular for *N*-terminal determinations in proteins and for manual Edman degradation. In addition, dansylation has also been used as one of the most sensitive methods for quantitative amino acid analysis.

Two-dimensional TLC on polyamide sheets using water-formic acid (200 : 3, v/v) for the first-direction run and benzene-acetic acid (9 : 1, v/v) for development at right angles to the first run has mostly been employed in conjunction with the Edman dansyl technique for sequencing peptides. These solvents cannot resolve Dns-Glu/Asp, Dns-Thr/Ser, and α -Dns-Lys/ ϵ -Dns-Lys/Arg/His. However, a third run in ethyl

Table 8 Characteristic colours of PTH amino acids following ninhydrin application

<i>PTH derivative</i>	<i>Colour properties</i>	<i>NH₄OH colour change</i>
Proline	UV, colourless	Light blue after heating
Alanine	Purple	Deeper colour
Glycine	Orange	
Serine	UV, purple	
Serine breakdown	Faint orange	Weak red
Asparagine	Yellow	More intense
Carboxymethylcysteine	UV, purple	
Methioninesulfone	Light tan	
Methionine	Faint tan	
Lysine	Very faint pink	Weak blue after heating
Tyrosine	UV, yellow before spray	Intense yellow
Threonine	Colourless	Light tan
Glutamine	Dark green	Dark blue
Phenylalanine	UV, colourless	Faint yellow
Tryptophan	UV, yellow before spray	Deep yellow
Aspartic acid	UV, pink	Darker
Glutamic acid	Grey	Dark blue

Silica gel plates, without fluorescent indicator, developed in heptane–CH₂Cl₂–propionic acid (45 : 25 : 30) and xylene–MeOH (80 : 10), sprayed with iodine–azide and 1.7% ninhydrin in MeOH–collidine–HOAc (15 : 2 : 5), heated at 90°C for 20 min; colour changes by blowing a saturated ammonia atmosphere over ninhydrin plate.

acetate–acetic acid–methanol (20 : 1 : 1) in the direction of solvent 2 resolves Dns-Glu/Asp, and Dns-Thr/Ser. A further run in the direction of solvent 2 and 3 using 0.05 mol L⁻¹ trisodium phosphate–ethanol (3 : 1, v/v) resolves the monosubstituted basic Dns amino acids. Use of molarity ammonia–ethanol (1 : 1, v/v) as a third solvent for two-dimensional chromatograms, for the separation of basic dansyl amino acids in particular, has been effective. Most of the TLC systems reported up to 1978 required more than two runs for complete resolution of all Dns amino acids. A few solvent systems to yield separations of basic, acidic and hydroxyl derivatives in the presence of other amino acids without resorting to the third solvent system and *R_F* values are given in Table 9. Additionally, a large number of solvent systems for one- or two-dimensional resolution of dansyl amino acids on silica gel or polyamide have been summarized in Table 10. Bhushan and Reddy reviewed the TLC of dansyl, and DNP amino acids and evolved several successful and effective solvent systems for the resolution of almost all the dansyl amino acids on silica gel plates (Tables 11 and 12).

Detection of dansyl amino acids In all cases, dansyl amino acids, being fluorescent, have been detected under a UV lamp (254 nm).

DABITC Derivatives of Amino Acids

DABITC reacts with the NH₂-terminal end of an amino acid in basic media to give a 4-dimethylamino

azobenzene thiohydantoin (DABTH) amino acid via a DABTC derivative, in a manner similar to the Edman method, where a PTH amino acid is obtained by the reaction of phenylisothiocyanate (PITC). The presence of excess free amino acid does not, in any case, interfere with the analysis.

Two-dimensional TLC on polyamide sheets by ascending solvent flow is used to identify all DABTH amino acids except DABTH-Ile/Leu. No phase equilibrium is necessary; H₂O–acetic acid (2 : 1, v/v) is used for the first dimension and toluene–*n*-hexane–acetic acid (2 : 1 : 1, v/v) is used for the second. For discrimination between DABTH-Ile/Leu, one-dimensional separation on polyamide using formic acid–ethanol (10 : 9, v/v) or one-dimensional separation on silica gel (Merck) using chloroform–ethanol (100 : 3, v/v) is carried out. The successful identification of DABTH amino acids relies on skilful running of the small polyamide sheet and interpretation of the pattern of spots.

Detection of DABITC derivatives of amino acids The use of DABITC reagent during amino acid sequencing of proteins has distinct advantages over the use of dansyl chloride; for example, the colour difference between DABITC, DABTC derivatives and DABTH-amino acids greatly facilitates direct visualization and identification. DABTH amino acids are coloured compounds having absorption maxima at 520 nm in acid media ($\epsilon = 47\,000$). Thus, using the visible region, the quantitation and

identification of these derivatives become more convenient and sensitive (10 pmol on a polyamide plate). Exposure to HCl vapours turns all yellow spots to red or blue on polyamide sheets.

DNP Amino Acids

Use of DNP amino acids, formed by condensation of 1-fluoro-2,4-dinitrobenzene (FDNB) with the free amino group of an amino acid, was first described by Sanger in 1945, who identified DNP amino acids by paper chromatography. Since then many modifications in the methods of obtaining derivatives of

amino acids for sequence analysis and in identification of such derivatives have been reported, and the use of DNP amino acids for sequencing purposes is rapidly going out of practice. Nevertheless, the importance of DNP amino acids has not yet disappeared.

Kirchner presented considerable information on the analysis of DNP amino acids based on the literature available up to 1970. In one of the earlier methods, thin-layer plates (20 × 20 cm × 0.25 mm) were prepared from a mixture of 10 g of cellulose MN-300 and 4 g silica gel H (Merck), homogenized in 80 mL of water, dried overnight at 37°C and developed in the first dimension with two solvents successively: *iso*-propanol–acetic acid–H₂O (75 : 10 : 15) for 15 min and *n*-butanol–0.15 mol L^{−1} ammonium hydroxide (1 : 1, upper phase). The dried chromatograms were developed in 1.5 mol

L⁻¹ sodium phosphate buffer (pH 6.0) in the second dimension.

In almost all methods reported, the separation has been carried out in groups of water-soluble and ether-soluble DNP amino acids, and for each group mostly two-dimensional TLC has been performed. A few solvent systems for one-dimensional resolution of DNP amino acids on silica gel plates are shown in Table 13.

Detection of DNP amino acids The DNP amino acids have been visualized by UV light (360 nm with dried plates, or 254 nm with wet ones) or by their yellow colour, which deepens upon exposure to ammonia vapours. Thin layers of silica gel usually give an intense purple fluorescence for DNP amino acids under UV light, which masks the presence of very faint spots and decreases the colour contrasts. The cellulose-silica mixed layer gives much lower fluorescence and preserves the colour contrasts between various derivatives. Because of the photosensitivity of these derivatives, it is advisable to carry out their preparation and chromatography in the absence of direct illumination.

Resolution of Amino Acids and Derivatives on Impregnated Layers

The technique of incorporating a suitable reagent with the adsorbent, prior to applying the samples to the plates, originated from simple TLC and can be termed impregnated TLC. The reagents and methods used for impregnation are not to be confused with locating/spray reagents because the latter are required for the purpose of identification even on impregnated plates.

Methods for Impregnation

Of the various methods used for impregnation, one is mixing of the impregnating reagent with the inert support. A second approach is the immersion of the plates into an appropriate solution of the impregnating reagent carefully and slowly so as not to disturb the thin layer. Alternatively, a solution of the impregnating material is allowed to ascend or descend the plate in the normal manner of development; this method is less likely to damage the thin layer. Exposing the layers to the vapours of the impregnating reagent or spraying the impregnating reagent (or its solution) on to the plate have also been employed; spraying provides a less uniform dispersion than the other methods. Another approach is to have a chemical reaction between the inert support and a suitable reagent: the support is chemically modified before making the plate, the compounds of interest are bonded to the reactive groups of the layer.

The impregnating agent participates in various mechanisms in the resolution process, including ion-pairing, complex formation, ligand exchange, coordination bonds, charge transfer, ion exchange and hydrogen bonding.

Amino acids Resolution of amino acids has been reported to be very rapid and improved by using copper sulfate, halide ions, zinc, cadmium and mercury salts, and alkaline earth metal hydroxides as impregnating materials and some of the results are described in Tables 14–17. The chromatograms developed in these systems provide compact spots, without lateral drifting of the solvent front. C₁₈ layers impregnated with dodecylbenzene sulfonic acid are helpful in confirming the presence of an unknown amino acid in a sample and the migration sequence on these impregnated plates is reversed, probably due to an ion exchange mechanism. Separation of α -amino acids with butan-1-ol-acetic acid-water (3 : 1 : 1, v/v), butan-1-ol-acetic acid-chloroform (3 : 1 : 1, v/v), and butan-1-ol-acetic acid-ethyl acetate (3 : 1 : 1, v/v), on plain and nickel chloride impregnated plates has been reported; the partition and adsorption coefficients for the amino acids under study were determined on both untreated and Ni²⁺ impregnated silica gel in a batch process and correlations were drawn between TLC separation of amino acids on the impregnated gel with adsorption/partition characteristics. The results indicate a predominant role of partitioning in the separation. Application of antimony (V) phosphate-silica gel plates in different aqueous, nonaqueous and mixed solvent systems has also been reported. Some impregnated TLC systems for resolution of amino acids are summarized in Table 18.

PTH amino acids As mentioned above, certain difficulties in resolving or identifying various PTH amino acid combinations have successfully been removed and multicomponent mixtures separated with metal impregnated silica gel layers, while other reagents such as (+)-tartaric acid and (–)-ascorbic acid have been used for the resolution of enantiomeric mixtures. The methods reported provide very effective resolution and compact spots (by exposure to iodine vapours) and can be applied to the identification of unknown PTH amino acid; some of these are given in Tables 19–21. Some of the successful solvent systems for TLC of PTH amino acids on impregnated plates are summarized in Table 22.

High performance TLC (HPTLC)/overpressured TLC (OPTLC) Improvements in the solid-phase materials for TLC have resulted in an increase in

not achieved initially. A continuous multiple development on silica gel was able to separate 18 samples and standards simultaneously using five development steps with four changes in mobile-phase and scanning densitometry; typical results are given in Table 23. PTH-Leu/Ile/Pro have been identified by HPTLC using multiple wavelength detection. OPLC using chloroform–ethanol–acetic acid (90 : 10 : 2) for polar, and dichloromethane–ethyl acetate (90 : 10) for nonpolar PTH amino acids has been successful in their separation and quantitation; the method is claimed to be superior to HPTLC in having relatively increased migration distance, resulting in the resolution of complex mixtures containing a large number of derivatives. OPTLC and HPTLC on RP-8, RP-18, and home-made ammonium tungstophosphate layers have also been used for the analysis of DNP amino acids.

Separation of 18 amino acids on cellulose, silica gel and chemically bonded C_{18} HPTLC plates has been achieved. All of these plates contain a preadsorbent zone except the cellulose. Quantification is carried out by scanning standard and sample zones at 610 nm. hR_F values of amino acid standards on reversed-phase and on normal-phase layers in different solvents are given in Tables 24 and 25, respectively.

Resolution of Enantiomeric Mixtures of Amino Acids and Derivatives

The measurement of specific rotation is a common and accepted method for evaluating the enantiomeric

T = tailing.

purity of chiral compounds. The determination of enantiomeric excess (*ee*) values is influenced by the presence of impurities and changes in concentration, solvent and temperature, and requires the $[\alpha]_D$ value for the pure enantiomer. The availability of a reliable optically pure standard depends on the analytical method by which it had been resolved from the enantiomeric or racemic mixture of the compound in question. Though TLC provides a direct method for resolution and analytical control of enantiomeric

purity, there are few reports on TLC separation of enantiomers.

In general, the following approaches for the resolution of enantiomers have been used.

Indirect method

This method involves reaction of the enantiomeric mixture with a suitable chiral reagent to make the corresponding diastereomeric derivatives prior to chromatography; the choice of chiral selector is

limited due to the feasibility of its reaction with the analyte.

Direct method

1. This method uses a chiral stationary phase; it may be due to either natural chirality of the material as such, like cellulose, or some sort of synthesis of the phase.
2. Chiral discriminating agents are added to the mobile phase.

3. A suitable chiral reagent is incorporated, such as acid, base, an organic compound or a metal complex with the adsorbent during plate making, or at a stage before developing the chromatogram.

DL-amino acids Separation of D,L-tryptophan on a crystalline cellulose-coated plate in 1980 seems to be one of the first TLC reports. Applying the principle of ligand exchange, (2*S*, 4*R*, 2'*RS*)-4-hydroxyl-1-(2'-hydroxy dodecyl)-proline was used as the chiral

^aCompounds moved to solvent front on plates impregnated with sulfates of Mg, Mn and Fe. PS₁, PS₂, PS₃, untreated plates; M₁, M₂, M₃, M₄, treated with sulfates of Mg, Mn, Fe, and Co, respectively. R_F values are the average of at least five determinations. Developed in 30–40 min at 25°C ± 2°C, and exposed to iodine vapours to locate the spots.

selector to resolve several racemic α -amino acids on reversed-phase 18-TLC plates first immersed (1 min) in a 0.25% copper(II) acetate solution (MeOH–H₂O, 1 : 9, v/v), dried, and then immersed in a 0.8% methanolic solution of the chiral selector (1 min); the results are shown in Table 26. Ready-to-use *Chiral-plates*[®] are now marketed by Macherey-Nagel, Duren, Germany, and *Chir*[®] plates are marketed by Merck, Germany. Resolution of DL-methyl Dopa, and DL-Dopa is very successful on Chiralplates using

methanol–H₂O–acetonitrile (50 : 50 : 30, v/v) as the mobile phase and ninhydrin as the detecting reagent (Figure 1). The R_F values for L-Dopa and D-Dopa were reported to be 0.47 and 0.61, respectively, and the system is capable of resolving enantiomers in trace amounts, with the lowest level of detection of the D-enantiomer in L-Dopa samples being 0.25%. The resolution of enantiomers of α -substituted α -amino acids, and racemic mixtures of natural and nonnatural amino acids, N-methylated and

^aVarious concentrations of each of the impregnating reagent have been used.

N-formylated amino acids, and various other derivatives of amino acids has also been achieved on Chiralplates; typical results are presented in **Tables 27 and 28**. A novel chiral selector from (1*R*, 3*R*, 5*R*)-aza-bicyclo[3,3,0]-octan carboxylic acid has been synthesized and used as a copper(II) complex for the impregnation of reversed-phase 18 plates for ligand exchange TLC separation of amino acids and the results were comparable to those on Chiralplates®.

Chiral selectors such as (–)-brucine and Cu-L-proline complex are used to resolve enantiomers of amino acids (**Table 29**), and (+)-tartaric acid and (–)-ascorbic acid for the resolution of enantiomeric PTH amino acids (**Table 30**). The chiral selectors are mixed with silica gel slurry.

Resolution of tryptophans and substituted tryptophans on cellulose layers developed with copper sulfate solutions has shown that excess of Cu²⁺ ions decreases the chiral discrimination of the system, and development with aqueous α-cyclodextrin (1–10%) plus NaCl solutions (0.1, 0.5, 1.0 mol L⁻¹) showed the best results with aqueous 4% α-cyclodextrin–1 mol L⁻¹ NaCl solution; the results are comparable to Chiralplate®. It has been observed that chiral effects are essentially additive (for cellulose and α-cyclodextrin) and there is a strong temperature dependence for the chiral separations.

α- and β-cyclodextrins, hydroxypropyl-β-cyclodextrin and bovine serum albumin in the mobile phase

have provided enantiomeric separations of amino acids and derivatives. Chiral monohalo-s-triazines have been used for the TLC resolution of DL-amino acids. Racemic dinitropyridyl-, dinitrophenyl- and dinitrobenzoyl amino acids are separated on reversed-phase-TLC plates developed with aqueous-org mobile phases containing bovine serum albumin as a chiral agent.

Dansyl-DL-amino acids Reversed-phase TLC plates from Whatman are developed before application of dansyl amino acids in buffer A (0.3 mol L⁻¹ sodium acetate in 40% acetonitrile, and 60% water adjusted to pH 7 by acetic acid). After fan-drying, the plates are immersed in a solution of 8 mmol L⁻¹ *N,N*-di-*n*-propyl-L-alanine and 4 mmol L⁻¹ cupric acetate in 97.5% acetonitrile, 2.5% water for 1 h or overnight and left to dry in air. After applying the samples, the plates are developed in buffer A with or without *N,N*-di-*n*-propyl-L-alanine (4 mmol L⁻¹) and cupric acetate (1 mmol L⁻¹) is dissolved in it. The enantiomers are detected by irradiating with UV light (360 nm) to yield fluorescent yellow-green spots. Use of 25% acetonitrile is preferred for glutamic and aspartic acids and serine and threonine derivatives. *N,N*-di-*n*-propyl alanine can be prepared by the following procedure: L-alanine (17.8 g) is dissolved in ethanol (200 mL) and 10% palladium on activated charcoal catalyst (3 g) and

Silica plates impregnated with (–)-brucine, developed in *n*-butanol–acetic acid–chloroform (3 : 1 : 4, v/v), up to 10 cm.

nitrile (70 : 30) is added to give a final acetonitrile concentration of 38% or 47%. For the second dimension, the mobile phase is 8 mol L^{–1} N,N-di-*n*-propyl-L-alanine and 4 mmol L^{–1} copper(II) acetate dissolved in 0.3 mol L^{–1} sodium acetate in H₂O–acetonitrile (70 : 30, pH 7); the plates are developed in the second dimension using a temperature gradient. The method is reported to be applicable to the resolution of amino acids in a protein hydrolysate with quantitation by densitometry.

β -Cyclodextrin (β -CD) plates have been used successfully for the resolution of enantiomers of dansyl amino acids and β -naphthylamide amino acids. The plates are prepared by mixing 1.5 g of β -CD bonded silica gel in 15 mL of 50% methanol (aqueous) with 0.002 g of binder and acetate in 50/50 MeOH–1% aqueous triethyl ammonium acetate (pH 4.1). Some of the results are shown in Table 31.

A macrocyclic antibiotic, vancomycin, has been used as a chiral mobile-phase additive for the separation of 6-aminoquinolyl-*N*-hydroxy succinimidyl carbamate (AQC) derivatized amino acids and dansyl amino acids on chemically bonded diphenyl-Freversed-phase plates. Both the nature of stationary phase and the composition of the mobile phase have a strong influence on the enantiomeric resolution; typical results are given in Table 32. Another macrocyclic antibiotic, erythromycin, has been used as a chiral impregnating reagent for the resolution of 10 dansyl-DL-amino acids on silica gel plates (Figure 2); hR_F values and solvent combinations are shown in Table 33. Resolution of dansyl-DL-amino acids has recently been reported (Table 34) on thin silica gel plates impregnated with (1*R*, 3*R*, 5*R*)-azabicyclo[3,3,0]octan-3-carboxylic acid, which is an industrial waste material and a proline analogue non-proteinogenic α -amino acid.

Quantitation

TLC is supplemented with spectrophotometric methods for the quantitation of amino acids and their PTH and DNP derivatives.

Amino Acids

The scraped layer corresponding to each spot is extracted with 70% ethanol in a known minimum volume, and ninhydrin reaction is performed followed by spectrophotometry. Six to eight standard dilutions in an appropriate concentration range for each amino acid are prepared; 2 mL of amino acid solution and 2 mL of buffered ninhydrin are mixed in a test tube, heated in a boiling-water bath for 15 min, cooled to room temperature and 3 mL of 50% ethanol is added. The extinction is read at 570 nm (or 440 nm for proline) after 10 min. Standard plots of concentration versus absorbance are drawn for each amino acid. Materials consist of standard solutions of amino acids, acetate buffer (4 mol L^{–1}, pH 5.5), ethanol (50%), methyl cellosolve (ethylene glycol monomethyl ether), and ninhydrin reagent (0.9 g ninhydrin and 0.12 g hydrantin dissolved in 30 mL methyl cellosolve and 10 mL acetate buffer, freshly prepared). The concentration of the unknown sample is read from the standard plots. TLC densitometry can be used to determine 0.5 mg L^{–1} of phenylalanine in blood as an indicator of phenylketonuria.

PTH Amino Acids

The quantitation of PTH amino acids is carried out *in situ* or after elution. For *in situ* determination, the fluorescence-quenching areas of PTH derivatives are usually measured against the fluorescent background

at 254 nm. While using a Turner fluorometer fitted with a door for scanning chromatoplates, the position of the scanner, the standardization of time between scanning and the end of chromatography, the loading volume, the developing distance and the layer thickness are the important influencing factors for reproducibility. The quantitation of PTH amino acids is also carried out by measuring their UV absorbance after they have been eluted from the layer. The scraped layer is extracted with methanol overnight, centrifuged for 30 min at 300 rpm, and the spectra of the extracts are recorded in the range from 320 nm to about 230 nm. To obtain reproducible UV absorbances the layers must be washed with methanol prior to development, and with chloroform after the separ-

ation has been carried out. The quantitation of PTH amino acids has also been practised as follows: the developed chromatograms are exposed to iodine vapours and the brownish spots scraped off, eluted with 95% ethanol or ethyl acetate, and the iodine removed by warming the sample tubes in a warm-water bath. The optical densities are read at 269 and 245 nm, appropriate blank determinations are carried out, standard plots are drawn, and the concentration of the unknown sample is calculated.

DNP Amino Acids

Use of direct fluorimetric quantitation (fluorescence quenching) *in situ* has been recommended. Silica gel G plates are developed in chloroform–benzyl alcohol–acetic acid (70 : 30 : 3 v/v) and *n*-propanol–ammonia (7 : 3 v/v) and polyamide plates are developed in benzene–acetic acid (4 : 1 v/v). The spots are scanned using a Camag/Turner scanner, after being dried in a stream of air, at the scanning speed of 20 mm min⁻¹ and an excitation wavelength of 254 nm. Alternatively, the layer is scraped off the plate and extracted for 5 min, with 1 mL 0.05 mol L⁻¹ Tris buffer, pH 8.6, at room temperature. Then the slurry is removed by centrifugation and the clear liquid is

evaluated by measuring the optical density at 360 nm or at 385 nm for DNP proline. For a blank, a similar extract is obtained from a clear spot on the same layer.

Future Developments

TLC and HPLC are often looked at as competitive methods, but each has its own advantages. In HPLC, finding suitable separation parameters is frequently costly in terms of time and materials; therefore, a combination of the two by first optimizing the particular separation parameter with TLC is a step leading to considerable time-saving and cost for an analysis. TLC is suitable as a pilot technique for the

investigation of appropriate separation conditions, particularly because with TLC various phase systems can be checked at the same time without expensive apparatus. TLC will continue to serve as a useful method for daily routine control analyses to identify and determine the purity of a variety of compounds, including enantiomers, with ease and speed, and can be readily modified for new situations. A wide choice for separation conditions will always be available as various phase systems can be checked simultaneously.

AMINO ACIDS AND DERIVATIVES: CHIRAL SEPARATIONS

Copyright © 2000 Academic Press

Introduction

It is an interesting feature of life that in general its building blocks, whilst often containing chiral centres, are generally composed from optically pure single enantiomers. An excellent, and well known, example of this is provided by the amino acids as those found in mammals are all of the L-form. This being the case, why is there a need to resolve the enantiomers of amino acids?

The chiral separation of amino acids is important for a number of reasons. Perhaps the major reason for the pharmaceutical industry is the need for optically pure amino acids, of the required configuration, in order to prepare synthetic peptides, both for testing and as potential new drugs. In this case methods are needed to determine optical purity, and measure amounts of the unwanted enantiomer at the 0.1% level and for large-scale isolation for subsequent synthetic work. Another pharmaceutical example is provided by the sulphhydryl drug penicillamine where the

D-enantiomer is used to treat arthritis but the L-form is highly toxic, and the optical purity of the drug therefore clearly becomes an issue.

Another interesting reason for wishing to examine the ratio of different amino acid enantiomers is that, as a result of their slow racemization with time, it provides another means of dating archaeological samples. Other applications include the determination of the nature of the amino acids found in microbial peptides and polypeptides where D amino acids are not uncommon (e.g. as constituents of certain antibiotics).

Chiral separations involve the resolution of individual enantiomers that are chemically identical and only differ in the spatial distribution of their individual atoms or groups. As each isomer will contain the same interactive groups, the intermolecular forces involved in their retention will also be the same. Consequently, unless a second retention mechanism is invoked, in addition to those involving intermolecular forces, both enantiomers will exhibit identical retention times on all stationary phases and remain unresolved. A variety of chromatographic separation strategies have been developed to obtain the resolution of amino acids. These include gas, thin-layer and column liquid approaches. In the case of liquid chromatography these methods have

included enantiomer separation via chiral stationary phases (CSPs; for a detailed treatment of the various stationary phase types the reader is directed to the Further Reading and relevant encyclopaedia entries), chiral mobile phases (generated by the addition of a chiral selector to the eluent) or derivatization with a chiral reagent to form diastereoisomers. The methodology used will depend to a large extent on the problem to be solved (e.g. analysis or preparative isolation) and each of these methodologies for amino acids are detailed below.

Derivatization of Amino Acids to Form Diastereoisomers

One of the earliest strategies to be implemented for the separation of amino acid is the formation of diastereoisomeric derivatives using an optically pure chiral derivatizing reagent. These can then be separated relatively easily on conventional stationary phases with achiral eluents. The major difficulty with this approach is ensuring that the reagent is indeed 100% optically pure and that racemization (of either reagent or amino acid) does not occur during the derivatization reaction. Clearly, if attempting to determine optical purity at the 0.1% level, even a 99.9% pure reagent is not sufficient. However, if these conditions can be met, the methodology is easy and robust. A huge range of chiral derivatizing reagents have been prepared and many of these can be used for amino acids. These applications would include the use of, for example, substances such as Marfey's reagent (1-fluoro-2,4-dinitrophenyl-5-L-alanine amide), 2,3,4,6-tetra-O-acetyl-D-glucopyranosyl isocyanate (GITC) and similar compounds, or the fluorescent 1-(9-fluorenyl)ethylchloroformate (FLEC). In addition, it is possible to form highly fluorescent diastereoisomeric isoindoles from amino acids using O-phthalaldehyde and a chiral thiol. Whilst these examples are among the most common chiral derivatizing reagents, there are many others.

Chiral Selectors in the Mobile Phase

An alternative to forming covalent derivatives is to employ chiral mobile phase additives that will act as chiral selectors interacting selectively with the different enantiomers of the amino acids to effect a separation.

For amino acids, separation by chiral ligand exchange has been of considerable importance. In this context a chiral mobile phase can be generated by adding a chiral selector such as L-proline (or another amino acid such as L-arginine, L-histidine or substances such as *N,N*-di-isopropyl-L-alanine or *N*-(*p*-tol-

uenesulfonyl)-L-phenylalanine, etc.) and copper(II) ions to an aqueous/organic solvent. Factors which affect the complex formation include the metal (as indicated above, this is usually copper but zinc, nickel and mercury have also been used albeit with inferior resolution), the metal ion/ligand ratio (usually 2 : 1), the concentration of the metal/ligand complex and pH. For practical applications the pH of the mobile phase would normally be recommended to be in the range of 7–8 in order to be able to carry out chromatography on conventional reversed-phase columns (this pH preserves the integrity of the columns and higher pH values cause the precipitation of the copper complexes).

As well as chiral ligand exchange, some use has been made of the ability of the cyclodextrins to form inclusion complexes with amino acid derivatives. The cyclodextrins are produced by the partial degradation of starch followed by the enzymatic coupling of the glucose units into crystalline, homogeneous toroidal structures of different molecular size. The three most widely characterized are the α -, β - and γ -cyclodextrins which contain six (cyclohexamylose), seven (cycloheptamylose) and eight (cyclo-octamylose) glucose units, respectively. These cyclic, chiral, torus-shaped macromolecules contain the D(+)-glucose residues bonded through α -(1 \rightarrow 4) glycosidic linkages. The mouth of the torus-shaped cyclodextrin molecule has a larger circumference than at the base and is linked to secondary hydroxyl groups of the C2 and C3 atoms of each glucose unit. The cyclodextrins provide a ubiquitous means of separating enantiomers either as mobile-phase additives or when used to make chiral stationary phases (see below) and an example of this would be the use of β -cyclodextrin as chiral mobile phase additive for the resolution of dansylated amino acids on a conventional reversed-phase column (C_8).

Chiral Stationary Phases for the Separation of Amino Acid Enantiomers and their Derivatives

There are a number of types of chiral stationary phase that are used for the separation of amino acids and their derivatives and these include ligand exchange phases, protein-based phases, the Pirkle-type phases, molecular imprints, coated cellulose and amylose derivatives, macrocyclic glycopeptide phases, and cyclodextrin-based CSPs.

Amino Acid Enantioseparation via Chiral Ligand Exchange Phases

The separation of amino acids on chiral ligand exchange columns represents one of the earliest

methods for the resolution of these compounds, both free and as derivatives (e.g. dansylated). The original work was performed by Rogozhin and Davankov using resins containing optically active bi- and trifunctional α -amino acids loaded with a metal ion such as copper(II). More recently, more efficient columns have been prepared by bonding chiral amino acid ligands to silica gel. It is also the case that by using a long-chain alkyl-substituted chiral selector such as *N*-decyl-1-histidine to the mobile phase a 'dynamically coated' CSP can be prepared from a normal reversed-phase column. In such cases it is still necessary to continue to supply a small amount of the chiral selector in the mobile phase to ensure that the ligand leached from the stationary phase is constantly topped up. As with ligand exchangers used as mobile phase additives, the mechanism of retention involves the formation of complexes between the ligand (generally based on L-proline), a metal ion (usually copper(II)) and the amino acid itself. Separations are made using reversed-phase types of eluents. Because of the ease of use of ligand exchange chromatography with chiral mobile phases on standard reversed-phase columns, these may be more useful than dedicated stationary phases.

Amino Acid Enantioseparation via Protein-Based Stationary Phases

The protein-bonded stationary phases were some of the first to be developed and usually consist of natural proteins (e.g. bovine serum albumin, α_1 -acid glycoprotein, ovomucoid, etc.) bonded to a silica matrix. Proteins contain a large number of chiral centres of one configuration and are known to interact strongly with small chiral compounds for which they can exhibit strong enantiomeric selectivity. Some specific interactive sites on the protein provide the chiral selectivity, but there are many others that generally contribute to retention. Protein columns based on bovine serum albumin have been employed for the separation of the enantiomers of certain aromatic amino acids and various derivatives, including dansyl, *N*-(9-fluorenylmethoxycarbonyl)- (Fmoc), *N*-(fluorescein thiocarbamoyl)- (FITC) *N*-(2,4-dinitrophenyl) and *N*-benzoyl. The use of the reagent *N*-(chloroformyl)carbazole to provide highly fluorescent derivatives has enabled the resolution of the enantiomers of all of the protein amino acids often with high separation factors. Proteins have also been described as showing remarkable enantioselectivity towards *N*-acylated amino acids.

The mobile phases employed for this type CSP are generally composed of phosphate buffers (0.1–0.2 M) modified with a limited amount of propan-1-ol. The pH range normally employed is be-

tween 4.5 and 8.0 and for example, in the case of the *N*-benzoyl-derivatized amino acids, increasing pH results in decreased retention. In general the lower the buffer concentration (from 0 to 0.1 M) the better the retention; however, an effect of increased buffer concentration (above 0.2 M) has been observed for *N*-benzoyl derivatives. An increase in organic modifier concentration reduces the hydrophobic interactions of the solutes with the column resulting in shorter retention times. Whilst very useful for the determination of, for example, enantiomeric purity, protein phases tend to have rather limited sample loading capacity.

The Pirkle-Type Stationary Phases

The so-called Pirkle stationary phases (named after their inventor W. M. Pirkle) consist of relatively small molecular weight chiral substances covalently bonded to silica. Each bonded moiety contains a limited number of chiral sites (sometimes only one). Nevertheless, on account of their small size, there will be a larger number of interactive groups bonded to the silica and thus the probability of the solute interacting with a chiral centre is still very high. In addition, as the interacting molecule is relatively small, the extra-chiral contributions to retention are also comparatively small, and consequently the chiral interactions themselves represent a higher proportion of the total. It follows that chiral selectivity becomes a more dominant factor controlling retention with the Pirkle phases.

The Pirkle phases have also been used very successfully for the separation of many free and derivatized amino acids. The separation of the *p*-bromophenyl derivatives of the enantiomers of a number of amino acids is shown in Figure 1. The stationary phase was a naphthyl urea Pirkle stationary phase multiply-bonded to the silica. All of the enantiomers were separated and the analysis time was less than 50 min. Elution was achieved by progressively increasing the dispersive character of the mobile phase. Consequently, the chiral selectivity was probably dominated by polar interactions.

Amino Acid Enantioseparation via Coated Cellulose and Amylose Derivatives

Another useful type of chiral stationary phase for amino acids and their derivatives is based on the polymers of cellulose and amylose. Usually the polymers are derivatized to increase chiral selectivity or improve stability. The derivatized cellulose or amylose polymer is coated (not bonded) to a silica support. The fact that the chiral material is not bonded to the silica makes the material somewhat labile with respect to certain solvents.

Figure 1 The separation of a series of amino acid derivatives. The column was 10-cm long, 6 mm i.d. One mobile phase component (A) was 50 mM phosphate buffer (pH 6.0) and the second component (B) pure acetonitrile. The gradient used was isocratic for 12 min 30% (B), then programmed from 12 to 29 min from 30% (B) to 47% (B), then from 29 to 49 min 47–67% (B) and, finally, from 49 to 57 min, 67–93% (B). The flow rate was 1 mL min⁻¹. 1, L-serine; 2, D-serine; 3, L-threonine; 4, D-threonine; 5, L-alanine; 6, D-alanine; 7, L-valine; 8, D-valine; 9, L-methionine; 10, D-methionine; 11, L-leucine and isoleucine; 12, D-leucine and isoleucine; 13, L-tyrosine; 14, L-phenylalanine; 15, D-tyrosine; 16, D-phenylalanine; 17, L-tryptophan; 18, D-tryptophan; 19, L-lysine; 20, D-lysine; 21, L-cystine; 22, D-cystine. (Courtesy of Iwaki K, Yoshida S, Nimura N and Kinoshita T (1987) Optical resolution of enantiomeric amino acid derivatives on a naphthylethylurea multiple-bonded chiral stationary phase prepared via an activated carbamate intermediate. *Journal of Chromatography* 404: 117–122.)

Both cellulose and amylose contain five chiral centres per unit and thus the polymeric material offers a large number of chirally interactive centres and high probability of interaction. There are basically two common types of cellulose and amylose derivatives that are used as stationary phases. The first type are simple esters usually formed from the acid chlorides such as acetyl chloride or benzoyl chloride. The more stable, and probably the more popular derivatives, are the carbamates which can be synthesized from the appropriate isocyanate. The most useful cellulose- and amylose-based chiral stationary phases are probably those derivatized with the different substituted tris(3,5-dimethylphenylcarbamates). An example of the separation of *N*-benzyloxycarbonyl alanine ethyl esters on cellulose tris(3,5-dimethylphenylcarbamate) is shown in Figure 2.

The column was 25-cm long, 4.6-mm i.d., and the mobile phase was hexane–2-propanol (90 : 10 v/v). The stationary phase was operated in the normal

phase mode, consequently, retention and selectivity was again controlled by differential polar interactions.

Amino Acid Enantioseparation via Macrocyclic Glycopeptide Stationary Phases

There are three commonly used macrocyclic glycopeptides and they are the antibiotics vancomycin, teicoplanin and avoparcin all of which were introduced as chiral stationary phases by Armstrong. They contain a large number of chiral centres, together with molecular cavities in which solute molecules can enter and interact with neighbouring groups. Vancomycin, for example, contains 18 chiral centres surrounding three ‘pockets’ or ‘cavities’ which are bridged by five aromatic rings. Strong polar groups are proximate to the ring structures that can offer strong polar interactions with the solutes. This type of stationary phase is stable in mobile phases containing 100% organic solvent.

The macrocyclic glycopeptides have a higher loading capacity than the traditional protein phases and are more stable. They can also tolerate a much wider range of solvents than the cellulose and amylose phases.

The macrocyclic glycopeptide stationary phases can also be used very effectively for the separation of amino acids and their derivatives. The separation of the isomeric bromophenylalanines as their Fmoc derivatives formed by reacting them with 9-fluorinylmethylchloroformate is shown in Figure 3. The two enantiomers are very well separated indicating that the chiral selectivity of the teicoplanin stationary phase was extremely high. It should be noted, that the ‘pure’ (*S*) enantiomer actually contained a significant amount of the (*R*) enantiomer. The macrocyclic glycopeptide stationary phases often exhibit high selectivity for chiral substances of biological origin, perhaps due to their being biological products themselves.

Figure 2 The separation of *N*-benzyloxycarbonyl alanine ethyl ester on cellulose tris(3,5-dimethylphenylcarbamate).

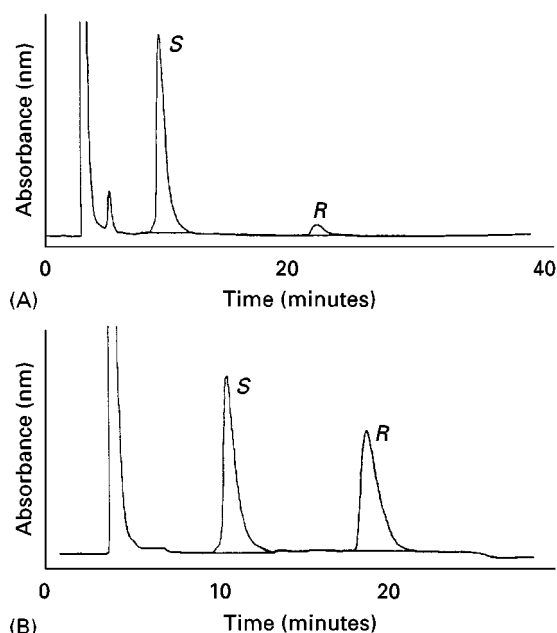

Figure 3 The separation of the enantiomers of 2-bromophenylalanine and 3-bromophenylalanine. (A) A 'pure' sample of the *S* enantiomer of Fmoc 2-bromophenyl alanine. (B) A racemic mixture of Fmoc 3-bromophenylalanine. The separation was carried out on a CHIROBOTIC T (teicoplanin) column, 25-cm long, 4.6-mm i.d., packed with 5 μ m particles. The mobile phase was programmed from methanol–1% triethylamine acetate (pH 4.5) (40 : 60 v/v) to methanol–1% triethylamine acetate (pH 4.5) (60 : 40 v/v) over 20 min. The flow rate was 1.0 mL min⁻¹ and the sample was injected as a solution in acetone. (Courtesy of Chirotech Technology Ltd.)

Amino Acid Enantioseparation via Cyclodextrin-Based Chiral Stationary Phases

In addition to the use of cyclodextrins as mobile phase additives discussed above, they have also been widely used for the preparation of CSPs. For this the three cyclodextrins, α , β and γ are bonded to a suitable support such as silica. An example of their use for the separation of three racemic *N*-*t*-Boc-amino acids is shown in Figure 4. It is seen that a very clean separation of the enantiomers is obtained. Other examples include the use of β -cyclodextrin columns for the resolution of dansylated amino acid derivatives and α -cyclodextrin columns for the separation of a variety of natural and synthetic amino acids and their derivatives.

Amino Acid Derivative Enantioseparation via Molecular Imprints

Molecular imprinted polymers (MIPs) are produced by preparing a polymer (usually prepared from a methacrylic acid, styrene or 4-vinylpyridine monomer template cross-linked with ethylenedimethylmethacrylate) in the presence of an imprint, or template, molecule. When the template is subsequently

removed it leaves a cavity capable of 'recognizing' and selectively rebinding the imprinted compound. This property allows discrimination between enantiomers and has been used as the basis for the development of CSPs for the highly selective separation of amino acid derivatives (e.g. dansyl, anilide, BOC-1-amino acid anilides, etc.) and a number of examples of this type of separation have been published. A typical example would be the use of a molecular imprint to the amino acid derivative L-phenylalanine anilide for the resolution of a mixture of the two enantiomers of the print molecule. In this case the more retained enantiomer is the L-form of the amino acid derivative as it exhibits a greater affinity for the stationary phase. In general the imprinted polymers are most selective for the particular print molecule used to prepare them. However, there are examples of the separation of enantiomers of non-imprint molecules as well.

Conclusions

As shown above there are various means for separating the enantiomers of amino acids and their

Figure 4 The separation of the enantiomers of three *N*-*t*-Boc-amino acids. The column used was 25-cm long packed with Cyclobond 1 RSP and operated at a mobile phase flow rate of 1.0 mL min⁻¹ at a temperature of -220°C . The mobile phase was 7% v/v acetonitrile–93% v/v% buffer (1% triethylamine, pH 7.1) and the separation was monitored with a UV detector at 225 nm. (Courtesy of San Chung Chang, Wang LR and Armstrong DW (1992) Facile resolution of *N*-tert-butoxycarbonyl amino acids: the importance of enantiomeric purity in peptide synthesis, *Journal of Liquid Chromatography* 15: 1411–1429.)

derivatives. These range from indirect methods such as the formation of diastereoisomeric derivatives or direct methods that exploit the spatial characteristics of different enantiomers by making them interact with a chiral stationary or mobile phase. This selectively enhances the standard free entropy of distribution of one amino acid enantiomer compared to the other and can provide adequate chiral selectivity to permit enantiomeric resolution. By one or other of these approaches the separation of the enantiomers of the majority of naturally occurring amino acids can be achieved by liquid chromatography.

Introduction

Advancement in modern biotechnology is mainly attributed to a detailed understanding of the structural features of proteins. This is predominantly accom-

plished by sequencing techniques and the analysis of amino acid composition. Irregularities in the structural characteristics of proteins, e.g. after translation of the protein, are determined by fragmentation to smaller peptides. Progress in the field of synthetic peptides utilizing synthesis based on these partial sequences depends on their immunological potential. The design of new specialized biomolecules such as hormones or neurotransmitters will have considerable pharmaceutical applications.

The large number of analytes and the small quantities present in biological samples have increased the demand for specific and sensitive analytical techniques. Capillary electrophoresis (CE) is capable of handling small sample volumes down to microlitre size with only a few nanolitres injected. High efficiencies, short analysis time and easy enantiomeric assays make CE an indispensable tool in the modern analysis of peptides and amino acids.

Amino Acids

Physicochemical Properties

In choosing an electrophoretic system it is important to consider both matrix and the structural features of the analytes. Whereas 18 amino acids are found after the hydrolysis of proteins, more than 50 derivatives are present in physiological fluids.

Amino acids are small, highly polar species. The individual species only differ in the residues *R*. Except for glycine this situation induces a chiral centre at the α -C-atom where two enantiomers (*R*-, *S*-) can be distinguished. Classifying these residues *R* by their impact on electrophoretic behaviour means a differentiation by their polarity or the generation of charge. Due to their zwitterionic nature, amino acids possess isoelectric points (pI); pH values equal to pI yield molecules without net charge and therefore no migration occurs in an electrical field. At pH values above the pI the molecules are negatively charged and migrate against the electroosmotic flow (EOF) towards

the anode, whereas lower pH values induce cations which migrate with the EOF towards the cathode.

Most amino acids lack suitable physical characteristics that can be exploited for detection. Only few species possess aromatic groups with high absorptivity, e.g. try, phe and tyr. In order to analyse native amino acids three strategies can be pursued. UV detection can be used at low wavelengths. A second approach is the application of indirect detection techniques. Detection concepts involving derivatization technology, especially fluorescence labelling, can also improve detection sensitivity.

Electrophoretic Systems – Separation Strategies

Analysis of native amino acids Direct UV detection at wavelengths below 220 nm takes advantage of the absorptivity of the carbonyl bond. Detection at such nonspecific wavelengths requires highly transparent buffers. Borate and phosphate are convenient electrolyte systems. Selectivity is mainly achieved by the optimization of pH because the analysis is performed with the native species.

In order to obtain cationic analytes, pH has to be adjusted to values lower than the first dissociation step ($pK \sim 2$). The stability of fused-silica capillaries is restricted to pH values above 2.5. Thus basic conditions with analytes migrating counter to the EOF are preferred. This separation mode benefits by prolonging the effective separation distance, keeping the electrical field strength constant so that higher resolution is achieved. Limits of detection are in the range of about $10^{-4} \text{ mol L}^{-1}$ (Figure 1).

Figure 1 Separation of amino acids and dipeptides in an infusion solution using direct detection at low wavelength. Capillary: fused silica 75 μm i.d., 65/73.5 cm; buffer: borate 40 mmol L^{-1} , pH = 11.0; $E = 408 \text{ V cm}^{-1}$, 191 nm; injection 50 mbar, 5 s. 1, Lys; 2, Pro; 3, Try; 4, Leu; 5, Ile; 6, Gly-Glu; 7, Val; 8, Phe; 9, His; 10, Met; 11, Ala; 12, Thr; 13, Ser; 14, Gly-Tyr; 15, Glu; 16, Asp.

Indirect UV detection was evolved for the analysis of small inorganic ions but it is also an efficient technique for analysis of a broad range of nonabsorbing components. This methodology is performed very easily with CE using a UV-absorbing electrolyte. With respect to dissociation behaviour, mobility and absorptivity the background electrolyte (BGE) has to be chosen carefully. As mentioned above, basic conditions should be applied to generate anionic species of amino acids. Therefore the BGE has to be negatively charged under alkaline conditions. Beside generating the background signal the nature of the electrolyte used has great influence on separation selectivity. Best resolution can be achieved with electrolytes of moderate mobility, e.g. salicylic acid ($\mu_{\text{pH}=11.5} = -6 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$). Salicylate at low mmol L^{-1} concentrations may also be used for indirect fluorescence detection. Concentration limits are in the range of $10^{-5} \text{ mol L}^{-1}$ (Figure 2).

Another approach to a universal, high sensitivity detection scheme is mass spectrometry (MS). Beside the very low limits of detection which are achievable, this technique provides information about molecular mass and structure. The compatibility of capillary zone electrophoresis (CZE) to MS can be attributed to the low flow rates in CZE. The main problem in coupling CZE to MS is the buffer. Further developments on suitable volatile buffers and interface types will extend the scope of applications.

Analysis of derivatized amino acids Many of the chemical reactions for labelling originate from peptide synthesis where they were used as protective groups or sequencing agents.

As a consequence of derivatization, amino acids change from small ionic species to large hydrophobic molecules. Differences in mobilities decrease. A sufficient separation selectivity is mainly achieved by micellar electrokinetic capillary chromatography (MEKC).

Many reagents have been investigated to improve sensitivity as well as suitability for fluorescence detection. Depending on the separation problem, further requirements have to be considered. The reagent must react quantitatively and reproducibly with primary and secondary amines to form stable products. Side reactions and fluorescence of the tag itself can interfere with the analysis. The choice of derivatizing agent is limited by these prerequisites.

The commonest applied systems are discussed below (Figure 3).

The classical agent ninhydrin is not used for derivatization in CE because the aldehydes formed cannot be separated.

O-phthaldialdehyde (OPA) was one of the first reagents developed for pre-column derivatization in liquid chromatography (LC). Strongly absorbing isoindoles with fluorescence properties are formed in a rapid reaction. The stability of the derivatives mainly depends on the amino acid and the reducing agent, e.g. thiols. Unfortunately, secondary amines are not derivatized. An increase in stability and detection sensitivity has been achieved by using naphthalene-2,3-dicarboxaldehyde (NDA) or 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde (CBQCA).

Phenylthiohydantoins (PTH) of amino acids are generated during Edman degradation of peptides. Maximum absorbance is found at 254 nm but the

derivatives lack fluorescence. Analysis is performed using phosphate or borate buffers under alkaline conditions. Surfactants such as sodium dodecyl sulfate (SDS) give a micellar pseudo-stationary phase allowing the partition process. In contrast to cationic surfactants, e.g. dodecyltrimethylammonium bromide (DTAB), analytical systems using anionic surfactants benefit from a wider migration time window. This can be mainly attributed to their counterosmotic migration behaviour (Figure 4).

Sulfonyl chlorides can convert primary as well as secondary amines. Well-known representatives are dansyl (DNS) and dabsyl (DABS) chloride. In order to separate all DNS amino acids, acidic buffers are used to reduce the EOF. In addition, neutral surfactants such as TWEEN 20 have been applied. The main disadvantage is the prolonged analysis time of about 70 min. Faster separations can be achieved using SDS with the penalty of a decrease in resolution. In some cases resolution can be enhanced by operating at lower temperatures (Figure 5).

Carbonyl chlorides such as fluorenylmethyl chloroformate (Fmoc) are more reactive than sulfonyl

chlorides. Fmoc amino acids fluoresce strongly and are stable at room temperature. Detection sensitivities in the nmol L⁻¹ range can be achieved.

Beside fluorescence detection, further improvements in sensitivity and specificity can be obtained with laser-induced fluorescence (LIF) techniques. A prerequisite is the match of emission wavelengths of the derivatized analyte with the spectral lines of the lasers. Great effort has been invested in the development of new fluorophores such as TRTC, CTSP, TBQCA, IDA and CBQ (Table 1).

Unfortunately, most of them are not commercially available.

Different derivatization techniques are applied: pre-column tagging is the commonest method. Several attempts have been made to transfer post-column methodology from LC to CE. A further promising technique is derivatization in the capillary because it simplifies automation. Reagent and sample are injected in succession. With the tandem mode a plug of reagent is injected into the column followed by the sample. A second technique is the introduction of an additional plug of reagent after the sample (sandwich

Figure 4 Separation of 20 PTH amino acids by MEKC. Capillary: fused silica 50 μm i.d., 59/67.5 cm, buffer: phosphate 25 mmol L^{-1} ; SDS 25 mmol L^{-1} ; pH = 9.0; $E = 444 \text{ V cm}^{-1}$, 260 nm; injection 50 mbar, 5 s. 1, Thr; 2, Asn; 3, Ser; 4, Gln; 5, Asp; 6, Gly; 7, Ala; 8, His; 9, Glu; 10, Tyr; 11, Cys; 12, Pro; 13, Val; 14, Met; 15, Leu; 16, Ile; 17, Try; 18, Phe; 19, Lys; 20, Arg.

mode). After a specified time for reaction, the separation can be performed.

Chiral analysis Assays of enantiomeric purity are easily performed by CE by simply adding the chiral selector to the running buffer. Two different methodologies are applied to achieve resolution. First, chiral distinction can be established by the formation of non-covalently bonded diastereomers.

The most widely applied cyclodextrins form host-guest complexes with one of the enantiomers preferentially. Compared to migration in the bulk phase, the complexed species possesses a different mobility. The separation occurs due to different complex stabilities resulting in different migration velocities. Enhancement of enantioselectivity is primarily attributed to cavity size (α -, β -, γ -cyclodextrin (CD)) and derivatization of the hydroxy moieties of

Figure 5 Separation of DNS amino acids by MEKC in an infusion solution. OPA, *o*-Phthalaldehyde; NDA, naphthalene-2,3-dicarboxaldehyde; CBQCA, 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde; PITC, phenylisothiocyanate; DNS, 5-dimethylaminonaphthalene-1-sulfonyl chloride; DABS, dimethylaminoazobenzenesulfonyl chloride; FMOC, 9-fluorenylmethyl chloroformate; FLEC, (*R*)-(*S*)-1-(1-fluorenyl)ethyl chloroformate; TRTC, tetramethylrhodamine isothiocyanate; CTSP, pyronin succinimidyl ester; TBQCA, 3-(4-tetrazolebenzoyl)-2-quinolinecarboxaldehyde; IDA, 1-methoxycarbonylinodolizine-3,5-dicarbaldehyde; CBQ, 3-(*p*-carboxybenzoyl) quinoline-2-carboxaldehyde.

the cyclodextrin (methyl-, hydroxypropyl-, sulfo-butyl-CD). Whereas compounds with a single aromatic core fit into α -CDs, β -CDs mainly form complexes with polynuclear aromates such as tyr or try. Larger structures are accommodated by γ -CDs. Most of the enantiomeric separations are performed using phosphate or borate electrolytes with native β - or γ -CD or mixed MEKC-CD systems which additionally contain a surfactant, mostly SDS.

Additives like urea or small amounts of organic solvents can improve the resolution.

Chiral surfactants such as *N*-dodecanoyl-L-serine (SDVal) or *N*-dodecanoyl-L-glutamate (SDGlu) have been investigated. These amino acids with hydrophobic alkyl chains are applied in a mixture with nonchiral surfactants, e.g. SDS.

Metal ions of copper(II), zinc(II) or cobalt(III) can be added to the electrolyte containing an L-isomer of an amino acid, e.g. L-proline, L-histidine or a dipeptide, e.g. aspartame. These metal-amino acid or metal-dipeptide complexes preferentially form a ternary complex with one enantiomer of the amino acid in the sample. Separation occurred due to different complex stabilities resulting in different mobilities for the individual enantiomers.

As a second approach, a racemic mixture of amino acids is derivatized with an optically pure reagent yielding covalent-bonded diastereoisomers. Reagents like GITC (2,3,4,6-tetra-*O*-acetyl- β -D-glucopyran-

osyl isothiocyanate) allow the application of non-chiral separation techniques. Detection sensitivity can be improved simultaneously by using reagents like FLEC ((*R*) or (*S*)-(1-fluorenyl)ethyl chloroformate) containing chromophores or OPA with a chiral thiol.

Peptides

Peptides are compounds of great medical interest due to their physiological role as hormones and neurotransmitters. Furthermore, considering peptides as subunits of proteins, peptide mapping after chemical or enzymatical cleavage allows characterization of the protein and to reveal metabolic disorders.

Physicochemical Nature of Peptides

The characteristics of peptides are situated between those of amino acids and high molecular weight proteins. Oligopeptides containing up to 15 amino acids behave similarly to amino acids. Short peptide chains cannot create a complicated conformation. In contrast, very long polypeptides with chain lengths up to approximately 100 units behave like small proteins. They exhibit characteristic features of secondary and tertiary structure.

Peptides exist in aqueous solution as amphoteric ions. Therefore peptides possess isoelectric points (pI). The peptide has net electroneutral properties at

the pI. The zwitterionic characteristics are influenced predominantly by the acidity of the medium. In acidic media the carboxyl group ($pK_a \sim 2.7\text{--}2.9$) is protonated and the peptide behaves as a cation. In alkaline media the protonated ammonium group is eliminated and the zwitterionic form is converted into an anion. The degree of dissociation is determined by the dissociation constants of the functional groups yielding different net charges.

A further feature to be considered in electrophoretic behaviour is the sequence of the amino acids. The dissociation constants of the individual residues are affected by the arrangement of the amino acids in the chain. Mass-to-charge ratios are altered and the peptide exhibits a different mobility.

Prediction of Electrophoretic Mobility of Peptides

A theoretical model of electrophoretic migration underlying the experimental approach can be very useful for the optimization of analytical conditions. It supports predicting peptide mobilities under different experimental conditions such as pH. If selectivity between closely migrating species has to be implemented, the model facilitates adjustment of the separation environment.

Furthermore, considering technical processes and purity control of peptide synthesis or enzymatic digestion of proteins, a defined relationship between apparent mobility and physicochemical parameters supports the identification of unknown species. Variation in the sequence of peptides can also be easily determined.

The mathematical description of the migration process is based on the contribution of two forces. The electrical field accelerates an ion with a force proportional to its charge. In addition, the ion is influenced by a retarding force which results from the viscosity of the medium and is connected to a size parameter.

For permanently ionized small ions a prediction of migration is easily achieved by applying Stoke's law which correlates mobility with $q \times r^{-1}$ and $q \times M^{-1/3}$ (q , charge and M , molecular mass). With larger, more complex aggregates like peptides both the charge and a suitable size parameter has to be ascertained. For computing the charge, the sequence of amino acids has to be considered as the environment of a residue affects the extent of ionization, e.g. neighbouring amide bond or acidic/basic residues at terminal amino or carboxylic groups. This means that the ionization constants of the free amino acids have to be adjusted. During the development of a theoretical understanding of migration phenomena, many approaches have been made considering mass, surface, radius and the number of units in a peptide chain as size parameter.

The following equation results from the semi-empirical approach by Offord relating electrophoretic mobility μ of peptides with their charge q and their molecular mass M :

$$\mu = k \times q \times m^{-2/3}$$

This linear relationship has been validated by experimental research; a large set of analytes covering collagen fragments, tryptic digest of human growth hormone (33 peptides), motilin fragments (24 peptides) and many additional peptides differ widely in charge and amino acid sequence. Nowadays several computer programs are available which are capable of calculating the charge-to-mass ratio just requiring the amino acid sequence.

Electrophoretic Systems – Separation Strategies

To optimize the separation of peptides, the experimental conditions have to be adjusted to emphasize differences in the charge-to-mass ratios of the analytes.

Apart from external parameters like electrical field, capillary dimensions (length, inner diameter) and temperature, separation is mostly influenced by the electrolyte. Intrinsic variables like type of buffer, mobility, ionic strength, pH and buffer additives determine electrophoretic and electroosmotic mobility.

In the first place selectivity in the analysis of peptides is controlled by pH. Altering the acidity of the separation medium affects both the charge of the peptide and the ionization of the capillary wall, resulting in the change in EOF.

The hysteresis-like course of the EOF shows the greatest variation in the pH range of approximately 5–7, i.e. near the dissociation constant of the silanol groups. For pH values below 3 or greater than 9, the influence of the superimposed EOF can be neglected and the migration of the peptide is almost independent from the EOF.

In acidic media (pH ~ 2) both basic and acidic residues of the peptide are protonated. Selectivity is attributed to the number of positive-charged ammonium groups in the chain resulting in different charge densities. Analytes migrate with the EOF. In high pH buffers (pH ~ 10), deprotonation of terminal and side chain ammonium groups (His) induces negatively charged species (presence of carboxylate groups) which migrate in the opposite direction to the EOF. At higher pH values the side chain amino groups of arg and lys are the only ones affected.

Optimization of pH values below 2 and above 12 is difficult to achieve since the limiting values of mobility are reached. Furthermore, due to the high conductivities of protons and hydroxyl ions, high currents

accompanied by Joule heating are generated. For practical purposes selectivity control for peptides with a majority of acidic moieties is mainly achieved in the range of pH 3–6 while basic residues are mostly affected at pHs around 10.

Additionally, isoelectric points of the peptides have to be included in the optimization strategy.

If peptides are obtained by chemical or enzymatic digests of proteins the cleaving agent has to be considered, e.g. trypsin cuts at the C-terminal side of lys and arg respectively. Thus fragments contain an excess of acidic residues. Selectivity can be easily affected in acidic media. Cleavage at aromatic or aliphatic side chains is performed with chymotrypsin or pepsin, yielding fragments with both acidic and basic residues and optimization can be extended to the full pH range (Figure 6).

Frequently used electrolytes for peptide mapping are phosphate, citrate and acetate as acidic buffers while borate or TRIS/Tricine are mainly applied under basic conditions. Phosphate and citrate are buffers that can be used over a broad pH range due to their multiple association constants. Borate exhibits very low conductivity compared to phosphate and other buffers. Buffer concentrations in the range of 10 mmol L^{-1} to approximately 100 mmol L^{-1} can be used. The electrolytes used should not possess any UV absorbance at low wavelengths.

An increase in ionic strength generates sharper peaks (zone focusing) due to the drop of the electrical field at the sample–electrolyte boundary and sample loading capacity can be increased. High ionic strengths induce high electrical currents and the in-

crease of Joule heating can give rise to band broadening.

Dispersive effects caused by the interaction with the capillary wall are usually not a problem with peptides but larger species can exhibit characteristics similar to proteins in that they tend to adsorb at the capillary wall.

High ionic strength, extreme pH values and buffer additives competing in adsorption with the peptides are strategies of optimization which can be adapted from protein analysis. At extreme pH values, peptides and the capillary wall are equally charged so electrostatic repulsion diminishes adsorption. Coated capillaries have been used to suppress this phenomenon.

High salt content in the sample may destroy the separation efficiency of the electrophoretic system so sample preparation steps must remove the high ionic strength in the sample.

Enhancement in selectivity can be attained if an additional equilibrium is superimposed on to the electrophoretic process. Mostly the additives used for this are complexing agents which interact with specific groups of the peptide.

As for amino acids, metal ions can be employed for the separation of peptides and histidine-containing peptides especially interact with zinc salts. Separation of two histidine dipeptides (L-L, D-L) can be attributed to favourable steric arrangement of the histidine residues in one isomer.

Cyclodextrins form dynamic inclusion complexes with hydrophobic parts of the peptide, e.g. with amino acid residues containing aromatic rings like phenylalanine. The mass of a complexed analyte is

Figure 6 Tryptic digest of a haemoglobin variant separated by CZE. Capillary: poly(vinyl alcohol) coated fused silica capillary $50 \mu\text{m}$ i.d., $50/57 \text{ cm}$, buffer: phosphate 50 mmol L^{-1} ; pH = 2.5; $E = 526 \text{ V cm}^{-1}$, 214 nm ; injection 0.5 psi , 5 s .

increased in this way and lower charge-to-mass ratio results in decreased mobility.

Ion-pairing reagents like short chain alkylsulfonic acids are particularly applied to adjust selectivity for hydrophobic peptides. Concentrations below the critical micellar concentration are used. The mechanism is based on the interaction between the hydrophobic surface of the peptides and the hydrophobic alkyl chain. Depending on the hydrophobicity of a peptide, different amounts of alkylsulfonic acid are attracted. Charge-to-mass ratios of the individual peptides are influenced to a different extent leading to the separation of the species.

A second approach to impart selectivity to large peptides with identical mobilities but different hydrophobicities is the use of ion-pairing reagents above their critical micellar concentration (CMC). This technique may also be used for peptides differing in neutral amino acids such as ala, val, leu or ile. MEKC takes advantage of the partitioning of the peptides between the electrolyte and the pseudo-stationary phase of the micelles. Hydrophilic moieties of the peptide interact with the outer polar sections of the micelle whereas hydrophobic parts are situated in the inner hydrophobic sphere. These peptide-micelle aggregates possess a different mobility compared to the electrophoretic mobility of the peptide in free solution.

Types of surfactants employed are divided into anionic, cationic and nonionic micelle-forming reagents. Because of the different charges, different migration directions are obtained. Negatively charged SDS, one of the most frequently used additives, migrates counter to the EOF and is used in concentrations up to approximately 150 mmol L^{-1} .

Common positively charged reagents are cetyl, dodecyl and hexadecyltrimethylammonium salts. These reagents invert the EOF at concentrations below the CMC so that as a consequence the polarity of the applied electrical field has to be reversed.

The addition of organic solvents such as methanol, ethanol, acetonitrile or tetrahydrofuran can provide selectivity for closely migrating peptides. These changes can be mainly attributed to solvation of side chains and variations in dissociation of the functional groups of the peptide. Additionally the EOF is modified due to altering the ζ -potential and the increase in buffer viscosity which generates a lower EOF and lower currents. In this way separations have been established for peptides differing in only a single neutral amino acid.

Peptides, especially large peptides with protein-like characteristics, sometimes tend to adsorb at the capillary wall. Beside the possibilities for avoiding dispersive effects mentioned above, the addition of amino-

or diamino compounds like diamino-pentane, butane or morpholine can diminish the peptide-wall interaction. Competing equilibria in the electrostatic attraction between analyte-silanol and amine-silanol groups suppress the adsorption of the peptide. Another approach to reduce adsorption is derivatization of the silanol groups with an uncharged polymer (coated capillaries).

Detection Techniques

The detection of peptides suffers from the same difficulties as described for amino acids. Additionally only a few amino acids (phe, try, tyr and to a lesser extent his, arg, gln, asn) provide residues with strong chromophores.

Measuring UV absorbance at low wavelengths ($< 220 \text{ nm}$) is the commonest mode of detection to give limits of detection of about $1 \mu\text{g mL}^{-1}$ ($\sim 10^{-5}$ – $10^{-6} \text{ mol L}^{-1}$) which are sufficient for most applications. Spectra obtained by a photodiode array detection support identification of impurities in peptide synthesis due mainly to the absence of the characteristic absorbance of aromatic residues at 220 nm (Figure 7).

Indirect techniques can be applied as for amino acids.

Detection of trace amounts of peptides requires more sensitive methods and sensitivity can be improved by fluorescence methods.

This approach faces the same difficulties as UV absorbance detection in that only try and, to a lesser extent, tyr and phe exhibit native fluorescence when excited at 280 nm (Xe-lamp). However, this 'natural specificity' facilitates selective identification of try-containing peptides. In addition, indirect fluorescence detection using salicylic acid for anionic charge peptides (basic buffers) or quinine for the positive mode (acidic buffer) have been applied.

To accomplish lower detection limits for a broader range of species derivatization techniques have to be applied and all the agents described for amino acids can be used for the derivatization of peptides.

Increased interest is being paid to mass spectrometric techniques for the characterization of peptides, especially soft ionization techniques like electron spray ionization (ESI). A promising approach towards nonfragmented peptides is the matrix-assisted laser desorption ionization with time-of-flight mass spectrometers (MALDI-TOF).

Concluding Remarks

CE has proved to be a versatile method for the high efficient separation of complex mixtures of amino

Figure 7 CZE separation of a peptide mixture. Capillary: ethylene/vinyl acetate dynamically coated with polyvinyl alcohol 75 μm i.d., 25/45 cm, buffer: phosphate 50 mmol L^{-1} ; pH = 2.5; $E = 155 \text{ V cm}^{-1}$, 200 nm; injection 50 mbar, 5 s. 1, Bradykinin; 2, angiotensin II; 3, α -MSH; 4, TRH; 5, LH-RH; 6, leucin enkephalin; 7, bombesin; 8, methionin; 9, oxytocin.

acids and peptides due to the manifold separation modes that can be applied. Short analysis times, easy manipulation of separation conditions and small injection volumes (nanolitres) are further advantages.

The field of biomedical and clinical amino acid and peptide analysis is still under investigation, especially as the transfer and adaptation of the separation modes to a broader range of real samples has to be established. Thus monitoring of *in vivo* processes, e.g. analysis of neurotransmitters in cerebrospinal fluid after online microdialysis, could be realized.

This is directly related to further improvements in reproducibility and detection strategies.

The most promising techniques that will fulfil the demands of trace analysis in biological fluids are CE-LIF and CE-MS.

Future trends are micro-fabricated CE devices implementing CE technology on a microchip and multiple capillary arrays allowing simultaneous analysis of up to 96 samples. Thus, a down-scaling of the analytical process and the performance of high throughput analysis could be achieved.

ANAESTHETIC MIXTURES: GAS CHROMATOGRAPHY

A. Uyanık, Ondokuz Mayıs University,
Kampus-Samsun, Turkey

Introduction

Today, anaesthetists normally use mixtures of nitrous oxide and oxygen as a background anaesthetic and carrier to introduce a potent volatile liquid

Figure 1 Molecular structures for the volatile liquid anaesthetics (A) halothane, (B) enflurane and (C) isoflurane.

anaesthetic such as halothane (2-bromo-2-chloro-1,1,1-trifluoroethane), isoflurane (1-chloro-2,2,2-trifluoroethyl difluoromethyl ether) or enflurane (2-chloro-1,1,2-trifluoroethyl difluoromethyl ether: **Figure 1**) to produce a state of anaesthesia and analgesia and to sedate a patient. Monitoring the patient's inhaled and exhaled breath during surgery is very important as a measure of the anaesthetic uptake and the depth of the anaesthesia. In operating theatres, therefore, physical methods of analysis (e.g. dedicated infrared analysers) are employed on account of their speed of response and continuous display facilities, though most can reliably handle only one component at a time. However, there is still the need to analyse such mixtures for all the major components, either in the course of research programmes involving different agents and different combinations such as inhaled or exhaled mixture analysis, blood and body fluid analysis, anaesthetic pollution studies, thermal decomposition studies or as a back-up to confirm the performance of the dedicated analysers. The major gases present in such mixtures, in addition to air, are carbon dioxide, nitrous oxide and halothane, isoflurane or enflurane (or cyclopropane, which is still in use in some places). If all the components (gases and vapours) need to be detected, gas chromatography is extremely powerful in the separation and quantification of the components, in comparison with the other techniques available.

Instrument Requirements and Procedures

There is no rigid boundary separating the basic instrumental requirements for conventional gas analysis and anaesthetic mixture analysis by gas chromatography. All the theoretical and practical knowledge and basic equipment of conventional gas analysis applies to anaesthetic mixtures and this simplifies the practice of the technique in this specialized field. A dual-column gas chromatograph fitted with a gas sampling valve (operated at room temperature), and equipped with a thermal conductivity detector (TCD) or preferably both TCD and flame ionization detector (FID) is most suitable for all the anaesthetic gas mixture analysis encountered. If a septum-type inlet system is also present, it should be placed next to the gas switching valve.

Sample Handling and Injection

Sample handling and injection techniques are greatly influenced by the source of the analysed samples such as liquid samples containing anaesthetics (e.g. blood, urine, sperm, tissue), low concentration gas samples (e.g. anaesthetics in pollution studies) and high concentration gas samples (e.g. inhaled and exhaled gas mixtures).

Direct injection of a liquid sample to the chromatographic column is very simple, but it is a rather crude approach and has serious disadvantages such as contamination of the sample port, column and detector, alterations in the baseline characteristics and interference by water vapour. The problems associated with the presence of the liquid in the chromatographic system are avoided by the technique of headspace analysis, whereby the vapour above the sample is injected under controlled conditions. Headspace sampling is rapid and is suitable for direct determination of the partial pressure of anaesthetics in blood.

Low concentration samples of liquid anaesthetics trapped in an adsorbent-filled cartridge (integrated sampling or passive dosimeter) in pollution studies are introduced into a gas chromatographic system via a gas sampling valve. Trapped anaesthetics are desorbed from the adsorption cartridge and transferred by the carrier gas to the main chromatographic column by heating the adsorption cartridge rapidly.

Low concentration (spot sampling) and high concentration samples in the gaseous state may be introduced to a gas chromatographic system by a gas-tight syringe (0.1–5.0 mL) with the usual septum-type inlet system. However, this is not a reproducible sample introduction method and creates problems of reliability where quantification of the components is needed. In addition to this, polymeric material such as rubber (e.g. on the barrel of a disposable syringe), plastics, and even glass itself adsorb liquid anaesthetics (~1–3%) on the contact surface. Adsorption on glass surfaces becomes more important when dealing with mixtures at lower concentrations (**Figure 2**). Therefore, syringe injection should be avoided in quantitative studies.

If gas samples are to be taken repeatedly to produce reproducible quantitative data, a gas sampling valve fitted with the desired size of sampling loop (0.25–10 mL) should be used at a constant temperature and filling pressure (usually ambient). It should be noted that, when using a concentration-sensitive detector such as TCD, the sample size and column diameter relationship must be taken into consideration to avoid column overloading. Several commercial gas sampling valves are available in various configurations. Some operate on the slider with the

Figure 2 Adsorption of halothane on glass surface at lower concentrations. Squares, cylinder preparation; circles, syringe dilution.

O-ring principle, while others operate by rotation of a Teflon® (polytetrafluoroethylene) or polyimide rotor in various flow paths. The analyst should be aware that some polymeric materials (e.g. silicone rubber O-rings) adsorb anaesthetic vapours to some extent (halothane > isoflurane > enflurane). Gas switching valves made of a stainless-steel body and Teflon® rotor or O-rings are the most suitable choice for anaesthetic purposes. It is important to note that gas sampling valves must not be used with flow control of the carrier gas, as this restricts the filling rate and hence the rate of flushing of the loop, resulting in tailing peaks. Pressure control is used instead.

Choice of Column

The column has an essential role in the separation process. Optimization of the separation process by suitable choice of chromatographic column, therefore, is the main starting point of any gas chromatographic analysis. Selection of a column is often made on the basis of the nature of the samples and the number of components to be analysed.

Capillary columns have been little used, and mainly for liquid anaesthetic analysis without gas components. The reason for this is the unfavourable retention factors of low boiling compounds on capillary columns operated at room temperature.

Packed columns may be subdivided as liquid partition and solid adsorbent columns. Almost all the anaesthetic gas analysis reported so far has been performed on packed columns of various lengths, either single or combined, commonly with 1/8 in and 1/4 in o.d. Liquid partition columns are generally employed to separate the high boiling or heavier components such as liquid anaesthetics, while solid adsorbent columns are used for the permanent gases (CO_2 , O_2 and N_2).

Synthetic porous polymer beads, which have been in widespread use as solid adsorbent packing material, are available commercially under a variety of trade names (Chromosorb Century Series, Porapak). Columns packed with porous polymer beads are more versatile and capable of separating each of the individual groups of components such as light gases and liquid anaesthetics at different temperatures as well as their complex mixtures with suitable temperature and column arrangements. No special treatment is required to obtain symmetrical peaks as they are chemically inert to the anaesthetic substances under the chromatographic conditions employed (usually 20–220°C). The combined effects of increasing viscosity of the carrier gas and expansion of the stationary phase as the temperature rises result in a very marked decrease in the carrier flow (Figure 3), e.g. a temperature rise from ambient to 200°C decreases the flow of the carrier from around 50 mL min⁻¹ to 20 mL min⁻¹ at 40 psig (2.7 bar) He inlet pressure, with a 2 m, 80–100 mesh Chromosorb 101 column. Nevertheless, the chromatography remains adequate and gives peaks for the liquid anaesthetics which are easily integrated. The size of the particles, expressed in mesh size, is very important in the column efficiency as the separation is provided by the surface and structure characteristics of the packing material. When the size of the particles is reduced, the column efficiency is increased and so is the inlet pressure because of the high pressure resistance of the column. At the present time, 80/100 mesh is the most widely used fraction; however, in instances where higher efficiency is needed, 100/120 mesh is frequently used.

Column Tubing Materials

Since most anaesthetic mixtures contain at least one volatile liquid component other than the permanent

Figure 3 Relationship of temperature to flow rate of a porous polymer packing (80/100 mesh). Flow rate = $3.86 \times 10^{-4} T^2 - 0.283 T + 59.6$.

gases, operating temperatures with solid adsorbent columns are considerably higher (e.g. 150–220°C) than those required for the separation of the permanent gas alone. Therefore, many of the commonly

used tubing materials for permanent gas analysis at lower temperatures may not safely be used in anaesthetic gas analysis. For example, anaesthetic vapours (particularly halothane) tend to decompose in contact with metals (or metal/metal oxide) such as aluminium (~200°C) and copper (>250°C) at elevated temperatures, producing a number of halogenated products. Relatively inert materials such as glass and stainless steel may safely be used as column tubing materials for anaesthetic separation purposes at high operating temperatures. Since mixtures contain large amounts of oxygen, heated septum-type injection ports should have a glass liner to prevent metal–liquid anaesthetic contact at higher temperature settings.

Choice of Detectors

The most commonly used detectors in anaesthetic gas analysis are TCD, FID and electron capture detector (ECD).

TCD is concentration-sensitive and has been the most widely used in chromatographic analysis for the determination of gases, and for any applications in explosion hazard areas. If inorganic gases, besides

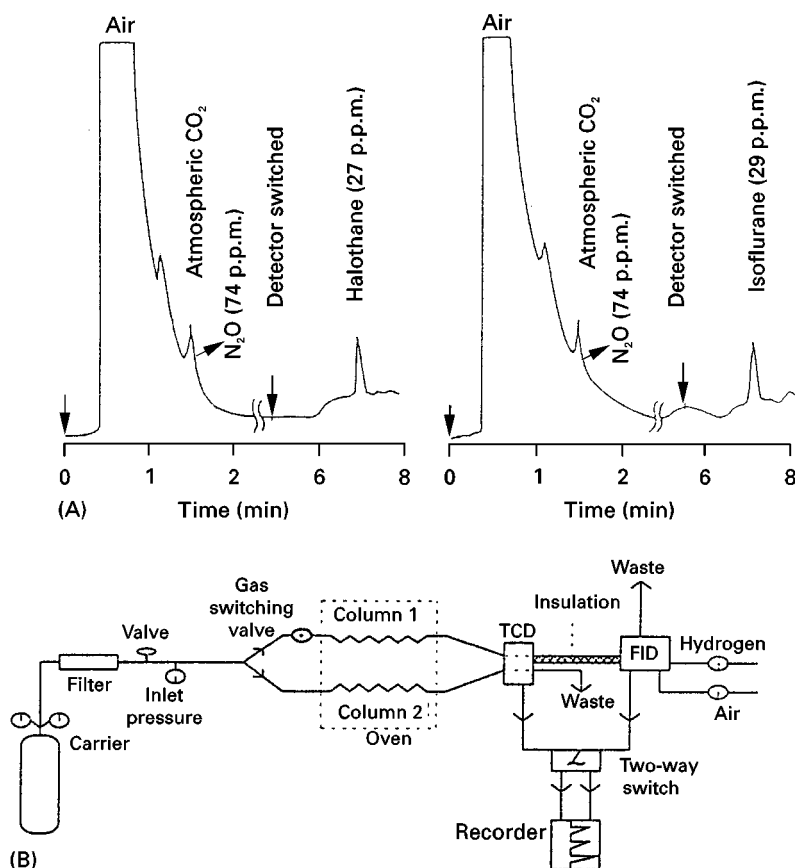

Figure 6 Chromatograms for dual detector chromatography (A) halothane (left) and isoflurane (right) in atmospheric air. (B) Simple set-up of a dual detector chromatograph.

liquid anaesthetics, need to be analysed, TCD is the detector of choice due to its universal response to almost all substances and its very large linear dynamic range. Because of its relatively poor sensitivity, it is unsuitable for the determination of low concentrations (<40 p.p.m.) without employing extreme detector conditions and large sample volumes. The nondestructive character of the TCD enables it to be used in dual-column chromatography by utilizing two channels simultaneously or in series with another detector such as the FID. Sensitivity of the hot-wire TCD depends on the temperature difference between filament and cell wall temperature (Figure 4), and higher chromatographic responses are obtained at higher filament temperatures.

The ECD is very sensitive to electrophilic species such as polyhalogenated anaesthetics and also to nitrous oxide, but its linear dynamic range is limited to a range of about 10^4 and it can easily be saturated. For this reason, it is generally employed for the low concentration determination of liquid anaesthetics and nitrous oxide. Since oxygen and water influence the detector sensitivity, these compounds must be rigor-

ously removed from the carrier and make-up gases. Contamination also causes serious interference. The detector must be held at an elevated temperature, always with a steady flow of carrier gas, and must be regularly baked out to ensure cleanliness. All these factors make ECD a difficult detector in anaesthetic gas analysis.

The very widely used FID is a mass-sensitive detector, with the disadvantage compared to the TCD that it is destructive. It responds to virtually all organic components but does not respond to the permanent gases. In the great majority of studies where only the determination of the volatile liquid anaesthetics is needed (e.g. blood and body fluid analysis), FID is used. If the analysis includes nitrous oxide in addition to liquid anaesthetics, the ECD alone may be chosen. For low concentration analysis, TCD and FID may be connected in series to determine the permanent gases and the liquid anaesthetics.

Choice of Carrier Gas

Choice of the carrier gas depends on the detector employed. For FID and ECD, carrier gas is not critical

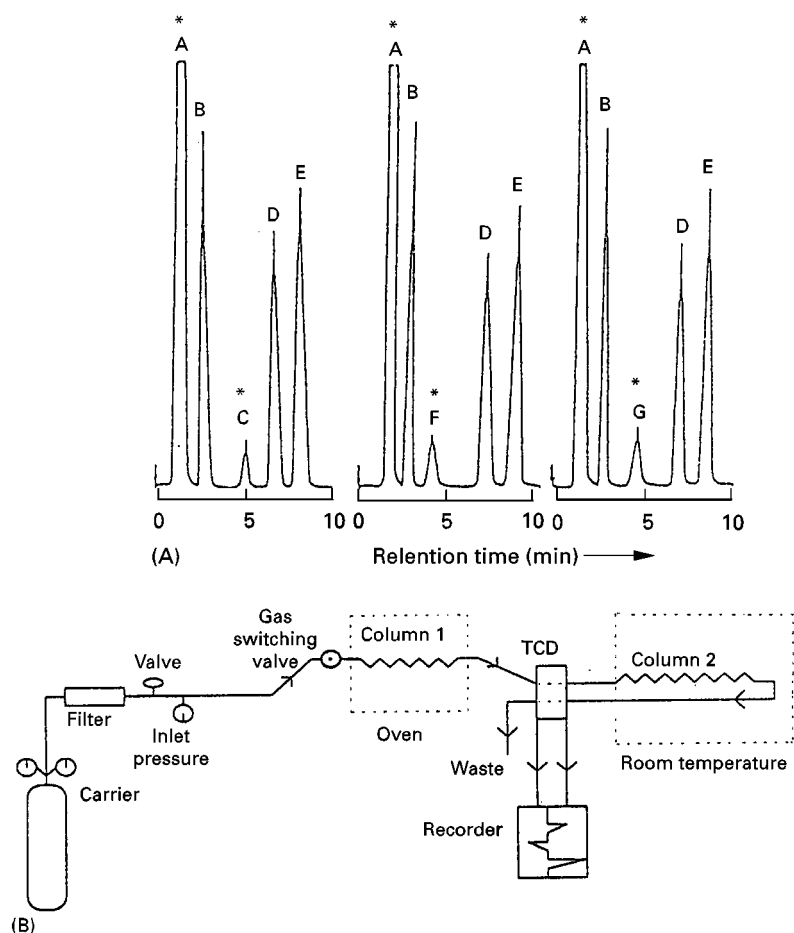

Figure 7 (A) Gas chromatograms for the dual-column separation of A, combined peak; B, air; C, halothane; D, carbon dioxide; E, nitrous oxide; F, isoflurane; G, enflurane; *, converted peaks. (B) Simple set-up of a temperature-programmed (linear or nonlinear) single-column chromatography.

and nitrogen may be used for most chromatographic purposes in anaesthetic analysis. For the operation of the TCD, hydrogen and helium give the highest sensitivities, but helium is preferred on safety grounds.

Tactics for the Anaesthetic Gas Analysis

It is usually required to measure a number of the components in an anaesthetic mixture (e.g. vapours and permanent gases), and a single column in a single isothermal run rarely meets this need. Although isothermal operation is preferred whenever possible, temperature programming may be used to improve the separation process. The magnitude of the temperature range depends on the sample components and the nature of the column packing materials. The disadvantage of temperature programming is that time is required at the end of an analysis to return the initial column temperature.

Using temperature as a variable is not, however, the only approach. Improved separations can be achieved by employing mixed column packing materials in various proportions and column lengths (e.g. porous polymers and molecular sieves) and multicolumn (parallel or serially) arrangements operating in tandem or at different temperatures with single or multidetector systems. Utilizing these approaches in various multicolumn and detector combinations allows the analyst to separate most mixtures of anaesthetics and permanent gases. Figures 5–7 show the various arrangements with examples of the chromatograms obtained.

Quantitative Analysis

To be able to carry out quantitative work, the gas chromatograph must be calibrated with accurately prepared mixtures of known composition. Dynamic methods for calibration such as gas stream

Figure 8 Mixing time for halothane prepared in helium. Squares, 1.1% halothane at 8.5 bar; diamonds, 1.2% halothane at 5.0 bar; triangles, 1.4% halothane at 3.1 bar.

mixing, permeation, diffusion and evaporation generate continuous flows of mixtures of known composition and are generally employed in studies where large volumes of standards at low concentrations are needed. Static methods for producing standard gas mixtures are appropriate when relatively small volumes of mixtures are required at moderately high concentration levels and have been widely used in calibrating gas chromatographic instruments. The preparation of calibration mixtures in gas cylinders involves either volumetric or gravimetric mixing. Gravimetric methods in which the concentrations are determined from the mass of each component present in the cylinders irrespective of the temperature and pressure of the mixture represent the nearest approach to an absolute method, provided the mixture is homogenous. The mixing rate is inversely proportional to the total pressure and is rapid if thermal or mechanical agitation of some kind is introduced to cause turbulence in the gas (usually the cylinder is rolled in a horizontal position). Without mechanical mixing, equilibration is likely to take several days (Figure 8). Syringe dilution methods (even with all-glass syringes) are not suitable for calibration purposes, particularly at lower concentrations, due to the adsorption of the liquid anaesthetics (see Figure 2).

Quantitative evaluation may be performed either by peak height or by peak area. The most commonly used method is based on direct calibration with standard samples which bracket the anticipated values in the unknown sample. The correlation peak value versus concentration generally exhibits a linear plot. The basic condition for successful quantitative analysis is a high degree of constancy of operating conditions and the accuracy of the analysis is significantly affected by apparatus parameters, characteristics of the detector and the skill of the analyst.

Conclusions

It may be concluded that there is no lack of knowledge, equipment and method to perform gas chromatographic separation and quantitative evaluation of all types of anaesthetic mixtures from one to multicomponent mixtures (including light gases and gaseous anaesthetics) in this extensively described well-established field. Nevertheless, the time required for analysis means that gas chromatography is mainly used for anaesthetic research purposes. Separations taking 5–10 min are not acceptable to medical personnel who would require a time scale an order of magnitude less for analysis of patient's breath in an operating theatre. However, there is room for future improvements to simplify the column systems, developing fast and continuous methods with automated samplers to be able to monitor anaesthetic concentrations during surgery.

ANALYTICAL APPLICATIONS: DISTILLATION

J. D. Green, BP Amoco Chemicals, Hull, UK

This article is reproduced from *Encyclopedia of Analytical Science*, Copyright © 1995 Academic Press.

Distillation is a widely used technique in chemical analysis for characterizing materials by establishing an index of purity and for separating selected components from a complete matrix. The technique is even more widely used in preparative chemistry and throughout manufacturing industry as a means of purifying products and chemical intermediates. Distillation operations differ enormously in size and complexity from the semi-micro scale to the 'thousands of tonnes per annum' production operations. For analytical purposes the scale employed is usually bench-level.

Numerous quoted standard specifications refer to distillation ranges as criteria of purity or suitability for use, or as indicators of performance. Published standards for analytical reagents in the AnalaR range and similar documentation by the American Chemical Society refer to distillation ranges as criteria of purity for appropriate materials.

Distillation is the process that occurs when a liquid sample is volatilized to produce a vapour that is subsequently condensed to a liquid richer in the more volatile components of the original sample. The volatilization process usually involves heating the liquid but it may also be achieved by reducing the pressure or by a combination of both. This can be demonstrated in a simple laboratory distillation apparatus comprising a flask, distillation head, condenser and sample collector (**Figure 1**). A thermometer is included in the apparatus as shown to monitor the progress of the operation. In its simplest form this procedure results in a separation into a volatile fraction collected in the receiver flask and a nonvolatile residue in the distillation flask. When a distillation column is incorporated in the equipment (**Figure 2**), the evaporation and condensation processes occur continuously. This results in a progressive fractionation of the volatiles as they pass up the column. The most volatile components emerge from the top of the column initially and the less volatile components emerge later. By changing the receivers throughout the course of the distillation a separation or fractionation is effected. Eventually, all the volatiles will have passed over into the sample collectors and any

involatile residue present will remain in the distillation flask.

Principles

The underlying principles are conveniently illustrated by reference to a vapour-liquid equilibrium diagram (**Figure 3**). The diagram relates to a binary mixture containing components P and Q. The lower curve gives the composition of the liquid boiling at various temperatures whilst the upper curve gives the composition of the vapour in equilibrium with the boiling liquid. Points x and y therefore give the boiling points of the individual components P and Q respectively. For example, point A shows that at X degrees the vapour has a composition of approximately 90% P, whilst point B shows that the boiling liquid with which it is in equilibrium, has a composition of approximately 80% P. In a continuous distillation process, such as occurs in a distillation column, liquid of composition C (90% Q, 10% P) vaporizes to vapour of composition D which condenses to liquid of composition E. Subsequently liquid E becomes vapour F and liquid G (composition: 50% Q, 50% P). This continuous process of vaporization and condensation occurs in the distillation column until a volatile fraction leaves the top of the column and is removed from the process by being collected in the collection flask. At the same time the liquid in the distillation flask becomes progressively more concentrated in the involatile component.

Distillation techniques may be classified into several different types including:

- Distillation at atmospheric pressure
- Distillation under reduced pressure
- Steam distillation
- Molecular distillation (short-path distillation)
- Azeotropic distillation
- Isopiestic distillation

Distillation at atmospheric or reduced pressure produces a separation according to the general principles discussed in the introduction.

Steam distillation is a means of distilling that part of a sample that is volatile in steam at a lower temperature than would otherwise be the case. This method is typically used for removing phenols from an aqueous sample. A means of introducing steam into the distillation flask must be provided.

Figure 1 Simple distillation apparatus comprising distillation flask (DF), distillation head (DH), thermometer (T), condenser (C) and receiver (or collection) flask (RF). (Reproduced by permission of Longman Scientific & Technical from Furniss *et al.*, 1989.)

Molecular distillation, sometimes termed short-path distillation, is used principally for compounds normally having high boiling points. In such cases, very low pressures are needed to achieve the desired low boiling points. The apparatus is constructed such that the condensing surface is located only a short distance from the distilling liquid and the pressure is reduced so that the process is governed to a large extent by the mean free path of the molecules involved. Hence the terms short-path distillation and molecular distillation.

Azeotropic distillation occurs when a mixture of two materials distils at constant composition. This technique is commonly used to remove water from samples. As an example, toluene may be added to a complex sample containing water, the distillation

Figure 2 Distillation apparatus including distillation column (DC). (Reproduced by permission of Longman Scientific & Technical from Furniss *et al.*, 1989.)

Figure 3 Vapour-liquid diagram for a binary mixture of components 'P' and 'Q', illustrating the principles of distillation (see text for details).

process results in the toluene-water azeotrope distilling. The distillate can then be examined to determine the water content of the original sample.

Isopiestic distillation is a convenient way of producing metal-free aqueous samples of volatile acids. The 'crude' acid is placed in an open container, such as a beaker, in a desiccator containing also an open beaker of pure water. The acid vaporizes and subsequent condensation in the pure water produces an aqueous sample of the volatile acid without any of the involatile contaminants such as metals.

The alternative terms 'flash' distillation and 'fractional' distillation are sometimes used to describe some of the above procedures carried out in a particular way. Flash distillation effects a crude separation into volatiles and residue, whilst fractional distillation produces a series of 'cuts' of different volatility (or boiling point) ranges.

Additionally, there are other forms of sample purification and separation that are either a type of distillation or are related to a distillation process:

- Simultaneous distillation/extraction (see application section)
- Dean and Stark distillation (see application section)
- Simulated distillation (gas chromatographic technique)

Analytically, distillation is used for two principal purposes, firstly as a criterion of purity and secondly as a means of preparing a sample for analysis. Many specification tests include reference to a distillation range within the limits of which a stated percentage

of the material of interest distills. Alternative distillation may be used to separate volatiles from a sample prior to a suitable analytical technique being employed on the distillate or on the residue. Standard tests are documented that involve distillation as a sample pretreatment method prior to titrimetry, potentiometry and spectrophotometry.

It is of course essential, if meaningful comparative results are to be obtained, that the design and use of the apparatus are standardized for such determinations.

Apparatus

A wide variety of apparatus is available to satisfy the different distillation techniques. The appropriate design of apparatus depends upon the type of distillation to be performed, considering, for example, whether a vacuum is required or steam is needed. Descriptions of apparatus are to be found in a number of different texts (see the Further Reading). Standards referring to the design and use of distillation apparatus have been published by the British Standards Institute and the American Society for Testing and Materials. Simulated distillation, which is a gas chromatographic technique, is dealt with in a [recent] review by Robillard *et al.* and referred to in several standards.

Apparatus may be discussed in terms of the distillation flask, the distillation column, the condenser and the collecting flask(s). By far the most effort has been expended in the design and operation of the distillation column, which is at the heart of the separation efficiency. The form of the column, its size and the packing used are very influential upon the results that are achievable. A summary of some different types of columns is given in **Table 1** and of packings in **Table 2**.

Once apparatus has been chosen carefully to compare with previously used apparatus or to conform to standards, the operation of the equipment must be considered. The following factors are among the most important to be controlled:

- The heating of the distillation flask must be carefully controlled.
- The distillation column must be operated so that it does not become flooded.
- The reflux ratio, that is the ratio of material returning via reflux to the distillation column or the distillation flask compared to the amount presented to the condenser in unit time must be carefully controlled. The higher the reflux ratio, the purer the material collected from the distillation. Reflux ratios are controlled in simple distillation appar-

Table 1 Types of distillation column

Column type	Description/comments
Duflon	An open tube into which a glass spiral fits closely
Hempel	A simple tube normally filled with a suitable packing (rings/helices) and having a side-arm near the top
Oldershaw	A column with fixed but perforated plates that maintains a fixed amount of liquid on each plate
Podbielniak	A simple tube with a wire packing to provide large contact area between liquid and vapour to effect high efficiencies
Spinning band	A tube fitted with a closely fitting spiral of PTFE or metal gauze that can be rotated at typical speeds of 600 to 3000 rev min ⁻¹ as the vapour-liquid equilibrium is maintained in the column
Vigreux	A tube having pairs of indentations down its length that slope downwards and provide a large and designed surface area to enhance the liquid-vapour equilibrium

atus by adjustment of the heating rate and by maintaining stable thermal conditions throughout the apparatus.

Applications

Documentation of analytical applications of distillation is widely dispersed. However, there are numerous references to distillation as a means of characterizing materials and as means of sample pretreatment in the lists of BSI standards, the ASTM methods documentation, the analytical methods of the Institute of Petroleum and those of other worldwide standards organizations. **Table 3** gives a selection of standards involving distillation originating from various standards organizations.

Table 2 Distillation column packings

Packing	Description
Balls	Mostly made of glass. Columns have a tendency to flood easily
Helices	Made from metal or glass, although metal may be packed mechanically to produce a more uniform column
Rings	Usually made of glass of an appropriate size for the column but can be made of porcelain, stainless steel, aluminium, copper or nickel. Depending upon design they can be termed Raschig, Lessing or Dixon rings
Wire packings	Produced as 'Heli-Grid' and 'Heli-Pak' packings especially for use with Podbielniak columns

Distillation is used widely to determine the moisture or water content of a variety of samples from petroleum products to cereal feeds. The technique used is one of azeotropic distillation using a codistillate such as toluene. Table 3 includes a selection of the available methods. Dean and Stark provided a particular design of apparatus that can be used for determining water content following azeotropic distillation with an immiscible organic solvent. As the azeotropic distillate condenses, the water separates from the immiscible organic and can be estimated directly in a specially graduated collection arm.

Some methods for the determination of water quality involve distillation, for example the determination of a 'phenol index', nitrate content or ammonium content.

The determination of nitrogen by the Kjeldahl method involves a preliminary distillation of the sample. Thus methods for the determination of ammoniacal and total nitrogen in ammonium nitrate, urea, sulfuric acid and fertilizers for industrial purposes involve a preliminary distillation followed by titrimetry.

Methods for the determination of available fluorine involve distillation prior to a potentiometric or spectrometric method.

The determination of distillation range is a method of establishing the purity of materials. Specific standard methods are available, for example, for methanol, ethylene glycol and propylene glycol. Many unpublished in company methods are used for products and intermediates to validate purity standards and to establish the suitability of materials for subsequent use.

As trace analysis of residual compounds in consumables has become more important, methods of extracting these compounds have been developed. A method known as simultaneous distillation extraction developed from the original work of Likens and Nickerson has been particularly popular and effective for extracting the volatiles from foods and plant materials, and the herbicide and pesticide residues in agricultural products. The method involves steam distilling the compound of interest from an aqueous suspension of the crude sample while the condensed steam is continuously extracted with an immiscible organic solvent refluxing within the apparatus. The design of the apparatus allows the volatiles that are extracted from the condensed water to be flushed into the flask containing the organic solvent. After a previously determined time of extraction, the apparatus may be disassembled and the organic solvent removed by evaporation from the now concentrated extract. Further analytical techniques can be used to identify and quantify the components of the residue according to the particular requirements.

A common application of distillation in the separation sciences is the purification and recovery of solvents especially from HPLC and GPC usage. There is a range of equipment supplied for recycling of solvents and useful sources of information can be found on the internet, for example the web pages for B/R Instruments and Recycling Sciences are included in the Further Reading.

The applications of distillation in analysis are widespread, with the technique being used to characterize materials and as a means of preparing samples prior to analysis. Standard apparatus and methods are described for many specific applications. Reference to the general texts and the standards detailed in the Further Reading will provide a source of information for future applications.

ANTIBIOTICS

High-Speed Countercurrent Chromatography

Introduction

Development of antibiotics requires considerable research effort in isolation and purification of the

desired compound from a complex matrix such as fermentation broth and crude extract. The purification of antibiotics by liquid-liquid partition dates back to the 1950s when the countercurrent distribution method (CCD) was used for separation of various natural products such as peptide antibiotics, aminoglycoside antibiotics and penicillin. However, CCD had serious drawbacks such as bulky fragile apparatus, long separation times and excessive dilution of samples. In the early 1970s an efficient continuous countercurrent separation method called countercurrent chromatography was introduced followed by the advent of high speed countercurrent chromatography (HSCCC) a decade later. Because of its high partition efficiency and speedy separation,

HSCCC has been widely used for separation and purification of natural products including a number of antibiotics as listed in Table 1. Being support-free chromatographic systems, HSCCC and CCD share important advantages over other chromatographic systems by eliminating complications arising from a solid support such as sample loss and decomposition.

Selection of Two-Phase Solvent System

Among the purification of natural products, the isolation of antibiotics is one of the most difficult tasks since the crude sample often contains, in addition to numerous impurities, a set of closely

related components that tend to exhibit similar partition behaviour in a given solvent system. Consequently, successful separation necessitates a painstaking search for a suitable solvent system, which often requires days, weeks and even months of hard trial. Once a suitable solvent system is found, however, the separation is usually completed within several hours.

HSCCC utilizes two immiscible solvent phases, one as a stationary phase and the other as a mobile phase. Solutes are subjected to a continuous partition process between these two phases along the column space free of a solid support, hence the separation is almost entirely governed by the difference between their partition coefficients.

Table 1 Separation of antibiotics by HSCCC

<i>Sample</i>	<i>Amount</i>	<i>Solvent system</i>	<i>Mobile phase</i>
Daunorubicin derivatives		Chloroform/ethylene chloride/hexane/methanol/water (1:1:1:3.5:1)	UP

Colistin	20 mg	<i>n</i> -Butanol/0.04 mol L ⁻¹ TFA (1:1)	LP

Generally speaking, the two-phase solvent system should satisfy the following requirements:

1. *Retention of the stationary phase.* Since the system eliminates the solid support, the retention of the stationary phase in the separation column entirely depends upon the hydrodynamic interaction between the two solvent phases in the rotating column under a centrifugal force field. While the hydrodynamic motion of the two phases is highly complex, the retention of the stationary phase may be predicted by the following simple procedure to measure the settling time of the two phases under gravity: Place 2 mL of each phase of the equilibrated two-phase solvent system into a 5 mL capacity graduated cylinder (alternatively, a 13 mm o.d. and 100 mm long glass test tube equipped with a plastic cap may also be used) which is then sealed with a stopper. Gently invert the cylinder five times to mix the contents and immediately place it on flat surface to measure the time required for the mixture to settle into two layers. This settling time should be considerably less than 30 s for stable retention of the stationary phase.

2. *Partition coefficient (K).* The partition coefficient is the key parameter for HSCCC. It is usually expressed by the analyte concentration in the stationary phase divided by that of the mobile phase. For a successful separation, the K value of an analyte should be close to 1. If $K \ll 1$, the analyte will elute close to the solvent front resulting in loss of peak resolution. On the other hand, if $K \gg 1$, the analyte will remain in the separation column for a long period of time, producing an excessively broad peak. In order to separate two components, the ratio between their partition coefficients, which is called separation factor (α), should be 1.5 or greater for a standard semipreparative multilayer coil HSCCC equipment providing a moderate partition efficiency of about 800 theoretical plates.

HSCCC Separation of Antibiotics

As mentioned earlier, HSCCC has been successfully applied to the separation of a variety of antibiotics (Table 1). The list includes peptide antibiotics, which are strongly adsorbed on the silica gel used as the stationary phase in column chromatography. Sample loading capacity of HSCCC widely varies from 1 mg to 10 g, depending on the tube diameter and the length of the multilayer coil used as the separation column. Two-phase solvent systems may be selected according to the hydrophobicity of the analytes, i.e. *n*-butanol solvent systems for hydrophilic groups, chloroform systems for moderately hydrophobic groups, and *n*-hexane systems for the most hydropho-

bic groups. Below, we describe the HSCCC separation of selected antibiotics including sporaviridins, bacitracins, colistins and ivermectins, especially focusing on the procedures for optimization of two-phase solvent systems.

The apparatus used in the following separations was a HSCCC-1A prototype multilayer coil planet centrifuge (Shimadzu Corporation, Kyoto, Japan) with a 10 cm orbital radius which produces a type-J synchronous planetary motion at 800 rpm. The multilayer coil was prepared by winding about 160 m of PTFE (polytetrafluoroethylene) tubing onto the column holder. Unless otherwise indicated, all separations were performed under the following conditions: speed of revolution: 800 rpm; stationary phase: organic phase; flow rate: 3 mL min⁻¹; elution mode: head to tail.

Sporaviridins

Sporaviridins (SVD, Figure 1) are basic water-soluble antibiotics produced by *Kutzneria viridogrisea* (formerly) *Streptosporangium viridogriseum* and they are active against Gram-positive bacteria, acid-fast bacteria and trichophyton. As shown in Figure 2, they consist of six components each having a 34-membered lactone ring and seven monosaccharide units, one pentasaccharide (viridopentaose) and two monosaccharides.

The SDV complex is soluble only in polar solvents such as water, methanol and *n*-butanol, and is extracted with *n*-butanol from the fermentation broth. Therefore, a two-phase solvent system containing *n*-butanol as a major organic solvent was mainly examined. We found that the SVD sample was entirely partitioned into the upper organic phase in a *n*-butanol/water binary two-phase solvent system (Table 2). This result indicated that the hydrophobicity of the *n*-butanol phase must be decreased to obtain a suitable partition coefficient. A nonpolar solvent such as *n*-hexane or diethyl ether was added to the *n*-butanol solvent system as a modifier. Initially, the volume of *n*-butanol was fixed at 10 mL while that of the diethyl ether was varied, and a two-phase system composed of diethyl ether/*n*-butanol/water (10:4:10) was selected. Next, the volumes of *n*-butanol and diethyl ether were fixed while that of water was varied from 11 to 14. At a solvent ratio of 10:4:12, almost evenly dispersed partition coefficients among the six components were obtained as shown in Table 2. Therefore, this solvent system was selected for the separation of the SVD components.

The preparative HSCCC separation of six components from the SVD complex was performed. In this experiment the retention of the stationary phase, elution time, and elution volume were 75%, 3.5 h and

Figure 1 Structures of sporaviridins. (Reproduced with permission from Oka H *et al.* (1998).)

500 mL, respectively. The six components were eluted in an increasing order of their partition coefficients yielding high purity of components A₁ (1.4 mg), A₂ (0.6 mg), B₁ (0.7 mg), B₂ (0.5 mg), C₁ (1.1 mg), and C₂ (1.4 mg) from 15 mg of the SVD

complex. HPLC analyses of the purified components are illustrated in **Figure 3**.

Bacitracins

Bacitracins (BCs) are peptide antibiotics produced by *Bacillus subtilis* and *Bacillus licheniformis*. They exhibit an inhibitory activity against Gram-positive bacteria and are most commonly used as animal feed

additives. Over 20 components are present in the bacitracin complex (Figure 4) among which BC-A and BC-B are the major antimicrobial components. BC-F is a degradation product and has nephrotoxicity. Only the structures of BC-A and -F have been determined (Figure 5).

We examined three groups of two-phase solvent systems containing *n*-butanol, ethyl acetate or chloroform as a major organic solvent, and ethanol and/or methanol as a modifier against water in each group. The *n*-butanol system produced suitable *K* values for

peaks 13–18 whereas those for peaks 20–22 are too large. The ethyl acetate system represented by ethyl acetate/ethanol/water showed a long settling time, suggesting poor retention of the stationary phase in the column. The most promising results were obtained from the chloroform, ethanol and/or methanol, water systems as summarized in Table 3. Among all combinations for the solvent volume ratio, chloroform/ethanol/ methanol/water (5:3:3:4) and chloroform/ethanol/water (5:4:3) gave the most desirable *K* values.

Figure 4 HPLC separation of bacitracins. Column Capcel Pak C₁₈ (5 μ m, 4.6 \times 150 mm); mobile phase, methanol/0.04 mol L⁻¹ sodium dihydrogen phosphate (6:4); flow rate, 1.3 mL min⁻¹; detection, 234 nm. (Reproduced with permission from Oka H *et al.* (1998) and Harada K-I *et al.* (1991).)

Figure 5 Structures of bacitracins A and F. (Reproduced with permission from Harada K-I *et al.* (1991) and Oka H *et al.* (1998).)

Figure 6 shows the countercurrent chromatogram of bacitracin components using the chloroform/ethanol/methanol/water (5:3:3:4) system. A 50 mg amount of the bacitracin complex was loaded into the HSCCC column. The retention of the stationary phase was 72.7% and the elution time was about 3 h. All components were eluted in an increasing order of their partition coefficients, yielding 5.5 mg of BC-A from peak 18 and 1.5 mg of BC-F from peak 22.

Ivermectins

Ivermectins B₁ are broad spectrum antiparasitic agents widely used for food-producing animals such as cattle and pigs. They are derived from avermectins B₁, the natural fermentation products of *Streptomyces avermitilis*. Avermectins B₁ have double bonds between carbon atoms at 22 and 23, whereas the ivermectins B₁ have single bonds in these positions (Figure 7). The ivermectins B₁ are a mixture of two major homologues, ivermectin B1a (> 80%) and ivermectin B1b (≤ 20%), but a crude ivermectin complex also contains various minor compounds (Figure 8A).

Table 3 Partition coefficients of the bacitracin components

Chloroform ethanol/ methanol/ water	Partition coefficients (UL^{-1})						
	Peaks	3, 14	17	18	20	21	22
5:2:3:4		7.20	2.46	4.17	0.64	0.65	0.48

(Reproduced with permission from Harada K-I *et al.* (1991) and Oka H *et al.* (1998).)

We selected a two-phase solvent system composed of *n*-hexane, ethyl acetate, methanol and water. This solvent system is conveniently used for the separation of components with a broad range of hydrophobicity by modifying the volume ratio between the four solvents. In the *n*-hexane/ethyl acetate/methanol/water (8:2:5:5) system first examined, the *K* values of the components corresponding to peaks 1–7 were 0, 0.46, 0.61, ∞, 1.86, 3.06, and 4.38, respectively.

Figure 6 HSCCC separation of bacitracin components. Apparatus, HSCCC-1A; revolution, 800 rpm; solvent system, chloroform/ethanol/methanol/water (5:3:3:4); mobile phase, lower organic phase; flow rate, 3 mL min⁻¹; detection, 254 nm. (Reproduced with permission from Harada K-I *et al.* (1991) and Oka H *et al.* (1998).)

Figure 7 Structures of ivermectins and avermectins. (Reproduced with permission from Oka H *et al.* (1996, 1998).)

This indicates that the component corresponding to peak 6 (ivermectin B1a) is mostly partitioned in the upper organic phase (Table 4). Although the *n*-hexane/ethyl acetate/methanol/water (9:1:5:5) system somewhat improved the *K* value of peak 6, it was still too large and the α value between peaks 6 and 7 is smaller than 1.5. Finally a slightly less polar solvent mixture at the volume ratio of 19:1:10:10 yielded the best *K* value, as indicated in Table 4. The settling time of this solvent system was 7 s, promising excellent retention of the stationary phase. In addition, the volume ratio between the two phases is nearly 1, indicating that either phase can be used as the mobile phase without wasting the solvents. Therefore, the above solvent was selected for separation of ivermectin components.

A 25 mg quantity of crude ivermectin was separated using the above solvent system at a flow rate of 2 mL min⁻¹. The retention of the stationary phase was 67.6% and the total separation time, 4.0 h. The HSCCC elution curve of the ivermectin components monitored at 245 nm is shown in Figure 9, where all components are separated into three peaks, A, B and C. HPLC analysis of each peak fraction and the column contents revealed that both HPLC and HSCCC systems elute all components in the same order: HPLC peaks 3, 5, and 6 correspond to HSCCC peaks A, B and C, respectively, while HPLC peak 7 was still retained in the HSCCC column. This separation yielded 18.7 mg of 99.0% pure ivermectin B1a (Figure 8B), 1.0 mg of 96.0% pure ivermectin

Colistin

Colistin (CL) is a peptide antibiotic produced by *Bacillus polymyxa* var. *Colistinus* that inhibits the growth of Gram-negative organisms. CL is a mixture of many components (Figure 10) where two main components are colistins A (CL-A) and B (CL-B). As shown in Figure 11, CLs-A and -B are linear-ring peptides that differ only in their *N*-terminal fatty acid. CL is used as a feed additive for domestic animals such as calf and pigs for preventing bacterial infection and/or improving feed conversion efficiency. CL is soluble in water, slightly soluble in alcohols, but insoluble in nonpolar solvents such as hexane and chloroform. From this property, we selected *n*-bu-

Figure 10 HPLC separation of commercial CL. Column, Chromatorex Ph ($5\ \mu\text{m}$, $4.6 \times 250\ \text{mm}$); mobile phase, acetonitrile/ $0.01\ \text{mol L}^{-1}$ TFA aqueous solution (24:76); flow rate, $1.0\ \text{mL min}^{-1}$; detection, $210\ \text{nm}$. (Reproduced with permission from Ikai Y *et al.* (1998) and Oka H *et al.* (1998).)

tanol and water as a basic solvent system. However, this combination was not suitable by itself, because the CL components were entirely partitioned into the aqueous phase. In order to partition the CL components partly into the *n*-butanol phase, various salts (NaCl and Na_2SO_4) or acids (HCl , H_2SO_4 and CF_3COOH or TFA) were added as a modifier. The desired effect was produced from TFA where the partition coefficients of CL components rose as the concentration of TFA in the solvent system was increased. This effect may be explained as follows: as shown in Figure 11, CLs-A and -B have five free amino groups in L-diamino-butyric acid (L-Dab), and these amino groups dissociate in the aqueous phase under neutral to acidic conditions. Since TFA forms an ion pair with these amino groups, the hydrophobicity of the CL components increases with the concentration of TFA resulting in their partition toward the organic phase. In order to determine the optimal concentration of TFA in the solvent system, K values of five components were measured at various TFA concentrations. As shown in Figure 12, the K value of each component increases with the TFA concentration, and at $40\ \text{mmol L}^{-1}$ TFA concentration, K values of CL-A and CL-B reached 1.5 and 0.6, respectively. At this TFA concentration, the α values between the adjacent peaks are all greater than 1.5, promising a good separation for all components. The settling time of the solvent system was 28 s, which is within the acceptable range. Therefore, we selected a solvent system of *n*-butanol/ $40\ \text{mmol L}^{-1}$ TFA aqueous solution (1:1) for the HSCCC separation.

Using the above solvent system, a 20 mg quantity of commercial CL was separated by HSCCC. The retention of the stationary phase was 45%. The

elution curve monitored at 220 nm is shown in **Figure 13**. According to the results of HPLC analysis and the elution curve, all collected fractions were combined into five large fractions as shown in **Figure 13**. The yields of CL-A and CL-B were 9 mg each and those of other minor components were 0.5–1.0 mg. HPLC analysis was performed for each fraction; as shown in **Figure 14**, the fractions of CLs-A and -B each produced a peak with a purity of over 90%.

Conclusions

Because it is a support-free partition system, HSCCC has an important advantage over other chromatographic methods in that it eliminates various com-

plications such as adsorptive loss and deactivation of samples as well as contamination from the solid support. As shown by our examples, HSCCC can isolate various components from a complex mixture of antibiotics by carefully selecting the two-phase solvent system to optimize the partition coefficient (K) of the target component(s). Compared with CCD and other countercurrent extraction methods, HSCCC can yield higher partition efficiencies in a shorter elution time. The HSCCC system can also be applied to microanalytical-scale separations without excessive dilution of samples. We believe that HSCCC is an

Introduction

High performance liquid chromatography (HPLC) has been widely used for the analysis of antibiotics because it is superior to conventional microbiological assays in terms of specificity, sensitivity and analysis time. In this article, HPLC conditions for the analysis of a variety of antibiotics are summarized. For analysis of biological samples, not only extraction methods but also derivatization methods are described, if necessary. Since it is not possible to list HPLC methods for all antibiotics in clinical use, only a few have been chosen from each class. Where a stereoisomer exists

for the antibiotic of interest, the HPLC conditions that are able to resolve stereoisomers are described.

Aminoglycosides

Aminoglycosides are analysed by reversed-phase HPLC. However, derivatization is usually necessary owing to very poor UV or visible absorption. For detection of aminoglycosides without derivatization, electrochemical, refractive index or mass spectrometric detection may be used.

Amikacin

For determination of amikacin (Figure 1, structure 1), the serum sample is loaded onto the silica gel column, followed by addition of *o*-phthalaldehyde (a derivatizing reagent). The column is eluted with 95% ethanol (pH 10) and the eluent is heated at 50°C. After cooling, the mixture is injected onto an ODS

Figure 1 Chemical structures of amikacin (1) and gentamycins C₁ (2), C_{1a} (3) and C₂ (4).

column. Mobile phase is methanol–water–acetonitrile (65 : 30 : 5) containing 0.2% tripotassium ethylenediamine tetraacetic acid (EDTA). Amikacin is detected fluorometrically at 350 nm for excitation and 420 nm for emission. The detection limit is 1 µg mL⁻¹. In order to resolve amikacin from its three isomers, a similar method is used except that the mobile phase is methanol–water (7 : 3). Tobramycin may be analysed with the same method.

Pre-column derivatization of amikacin is also conducted by addition of 1-fluoro-2,4-dinitrobenzene to plasma or urine, leading to formation of a stable chromophore, which can be detected at 360 nm. An ODS column is used with a mobile phase consisting of acetonitrile–water (68 : 32). The detection limit is 1 µg mL⁻¹. Amikacin may be extracted from serum using a cation exchange solid-phase extraction column prior to derivatization.

Gentamycin

Gentamycin in plasma is extracted with a cation exchange solid-phase extraction column (carboxy-

propyl-bonded silica column). Gentamycin is eluted with a 1 : 1 mixture of acetonitrile–0.2 mol L⁻¹ borate buffer (pH 10.5) and is derivatized with 9-fluorenylmethyl chloroformate. Derivatized gentamycin is analysed on an ODS column with a mobile phase consisting of acetonitrile–water (9 : 1). The derivatives are detected fluorometrically at 260 nm excitation, 315 nm emission, with a detection limit of less than 50 ng mL⁻¹. Gentamycins C₁, C_{1a} and C₂ are resolved (Figure 1, structures 2, 3 and 4, respectively).

o-Phthaldialdehyde, dansyl chloride, fluorescamine, 1-fluoro-2,4-dinitrobenzene or 2,4,6-trinitrobenzenesulfonic acid may also be used as derivatizing reagents.

Glycopeptides

Various glycopeptide antibiotics are separated with an ODS column. The mobile phase composition is either 7–32% acetonitrile (7% for 1 min, then increase to 34% over 13 min) in 0.1 mol L⁻¹ phosphate buffer (pH 3.2) or 5–35% acetonitrile (5% for 1 min, then increase to 35% over 13 min) in 0.025 mol L⁻¹ phosphate buffer (pH 6.0). Glycopeptides are detected at 220 nm.

Vancomycin

Serum is deproteinized with an ice-cold mixture of 10% trichloroacetic acid–acetone (2 : 1) and the supernatant is injected into an ODS column. The mobile phase consists of 50 mmol L⁻¹ sodium dihydrogen phosphate (pH 3.3)–acetonitrile (4 : 1) containing 1 mmol L⁻¹ sodium dodecyl sulfate. Vancomycin is detected at 235 nm with a detection limit of 1 µg mL⁻¹.

Macrolides

Clarithromycin

Clarithromycin (Figure 2, structure 5) and its major metabolite (14-hydroxyclearithromycin) are analysed with a C₈ column. The mobile phase consists of acetonitrile–methanol–water (39 : 9 : 52) containing 0.04 mol L⁻¹ sodium dihydrogen phosphate with the pH being adjusted to 6.8 using sodium hydroxide. The eluent is monitored by electrochemical detection with a quantification limit of 30 ng mL⁻¹. Plasma and urine are extracted with ethyl acetate–hexane (1 : 1).

Erythromycin

Erythromycin A (the major and most active component, Figure 2, structure 6), erythromycin B,

Figure 2 Chemical structures of clarithromycin (5) and erythromycin A (6).

erythromycin C and related compounds in commercial preparations are analysed with an ODS column using a mobile phase consisting of acetonitrile–methanol–0.2 mol L⁻¹ ammonium acetate–water (45 : 10 : 10 : 35, pH adjusted to 7.0–7.8). Erythromycins are detected at 215 nm.

Erythromycin and its metabolites in biological fluids are analysed with an ODS column using a mobile phase consisting of acetonitrile–methanol–0.2 mol L⁻¹ sodium acetate (pH 6.7, 40 : 5 : 55). Erythromycin is detected with a dual-electrode electrochemical detector with a detection limit of 10 ng mL⁻¹ in plasma. Erythromycin is extracted from plasma with ether, and urine is deproteinized with acetonitrile. Other related erythromycins and degradation products are also resolved.

Ivermectin

Ivermectin in tissue is analysed with an ODS column using a mobile phase of acetonitrile–water (9 : 1) at 65°C. Ivermectin is detected fluorometrically at 272 nm excitation, 465 nm emission, with a detection limit of 0.25 ng g⁻¹. Tissue sample is loaded onto a C₈ solid-phase extraction column, eluted with acetonitrile, and the eluate dried under a stream of N₂. The dried residue is dissolved with ethyl acetate–hexane (2 : 3), loaded on a silica column, and eluted with methanol–ethyl acetate (1 : 1). The eluate is dried under a stream of N₂ and treated with trifluoroacetic anhydride and methylimidazole. The analyte thus obtained is injected into an HPLC.

Penicillins and Cephalosporins

Many penicillins and cephalosporins are chiral, partly due to the chirality of the side chain. The D-epimers of ampicillin (see Figure 3, structure 13), cephalexin (Figure 3, structure 17) and cephaloglycin are more active than the corresponding L-epimers. Stereoisomers also exist for amoxicillin (Figure 3, structure 14), azidocillin, cefamandole, cefsulodin and cefibuten (Figure 3, structure 16). For these β -lactams, commercial preparations contain only a single isomer.

For some β -lactams, commercial preparations contain both epimers. These include carbenicillin (7), clometocillin, moxalactam (18), phenethicillin (11), propicillin (12), sulbenicillin (8), temocillin (9) and ticarcillin (10) (see Figure 3). Epimers of these β -lactams are resolved by reversed-phase HPLC.

Ampicillin

In order to separate ampicillin (Figure 3, structure 13) from penicilloic acid, phenylglycine and 6-aminopenicillanic acid, an ODS column is used with a mobile phase consisting of 35% acetonitrile in an aqueous solution of 3.5 mmol L⁻¹ sodium dodecyl sulfate and 0.2 mol L⁻¹ formic acid. Ampicillin and other compounds are detected at 254 nm. For separation of ampicillin from its degradation products, an ODS column is used with a mobile phase of 22.5% methanol in an aqueous solution of 5 mmol L⁻¹ tetrabutylammonium hydrogen sulfate and 5 mmol L⁻¹ ammonium sulfate (pH 2.6). Ampicillin and the degradation products are detected at 238 nm.

Ampicillin is analysed in biological fluids with an ODS column using a mobile phase consisting of 0.06 mol L⁻¹ phosphate buffer (pH 4.6)–methanol (425 : 75). Ampicillin is detected at 225 nm with a limit of accurate determination of 0.5 μ g mL⁻¹ in urine, plasma or saliva. Samples are deproteinized with perchloric acid.

In order to increase sensitivity, ampicillin and its metabolites in urine are subjected to postcolumn alkaline degradation following separation with an ODS column. Urine is diluted with water and injected directly. The mobile phase is an aqueous mixture of 5 mmol L⁻¹ sodium heptylsulfonate, 1 mmol L⁻¹ sodium dihydrogen phosphate and 9 mmol L⁻¹ phosphoric acid–methanol (1.5 : 1, pH 3.0). Degradation of ampicillin and its metabolites is conducted with 0.75 mol L⁻¹ sodium hydroxide, 2 mmol L⁻¹ mercuric chloride and 10 mmol L⁻¹ EDTA, and the degradation products are detected at 300 nm. The limits of accurate determination are 0.5 μ g mL⁻¹ for ampicillin and 1–2 μ g mL⁻¹ for the metabolites.

Figure 3 Chemical structures of carbenicillin (7), sulbenicillin (8), temocillin (9), ticarcillin (10), phenethicillin (11), propicillin (12), ampicillin (13), amoxicillin (14), cefixime (15), ceftibuten (16), cephalixin (17) and moxalactam (18).

Carbenicillin, Sulbenicillin and Ticarcillin

These epimeric, di-anionic β -lactams are similar in physicochemical properties and are analysed under very similar conditions. For analysis of carbenicillin (Figure 3, structure 7), plasma and urine samples are

loaded onto an anion exchange solid-phase extraction column. Carbenicillin epimers are eluted with 10% lithium chloride-methanol (3 : 2) and injected into an HPLC. Analysis is on an ODS column with a mobile phase consisting of 0.05 mol L⁻¹ ammonium acetate-methanol (9 : 1). Carbenicillin

Figure 4 Chromatogram of human plasma spiked with carbenicillin. Five hundred microlitres of human plasma was spiked with 20 μL of an aqueous solution of carbenicillin (5.2 mg mL^{-1}). R, R-epimer, S, S-epimer.

epimers are detected at 254 nm. The epimers are resolved to the baseline with the R-epimer being eluted prior to the S-epimer (Figure 4).

Similar methods can be applied for the analysis of sulbenicillin (Figure 3, structure 8) and ticarcillin (Figure 3, structure 10). For sulbenicillin, the mobile phase consists of 0.05 mol L^{-1} phosphate buffer (pH 7.0)–methanol (8 : 1). The epimers are resolved to the baseline with the S-epimer being eluted faster than the R-epimer. The detection limit is $0.5 \mu\text{g mL}^{-1}$ for each epimer. For ticarcillin, the mobile phase consists of 0.05 mol L^{-1} phosphate buffer (pH 7.0)–methanol (12 : 1). The epimers are resolved to the baseline with the R-epimer being eluted faster than the S-epimer.

Cefixime

Cefixime (Figure 3, structure 15) is determined on an ODS column with a mobile phase consisting of acetonitrile–water (2.75 : 7.25) containing 0.01 mol L^{-1} ammonium acetate and 0.01 mol L^{-1} tetra-*N*-butylammonium bromide. Cefixime is detected at 290 nm.

For analysis of cefixime in serum, an ODS column is used with a mobile phase consisting of 0.3% potassium dihydrogen phosphate–acetonitrile (88.5 : 11.5). For urine analysis, the mobile phase is a mixture of 0.15% potassium dihydrogen phosphate–acetonitrile (77 : 23) containing 0.1% phosphoric acid. Cefixime is detected at 254 nm with a detection limit of $0.1 \mu\text{g mL}^{-1}$.

Ceftibuten

Although commercially available formulations contain only the *cis* isomer (Figure 3, structure 16),

HPLC methods for determination of both *cis* and *trans* isomers have been developed because isomerization is observed *in vivo*.

Ceftibuten and its *trans* isomer are separated with an ODS column using a mobile phase consisting of 100 mmol L^{-1} ammonium acetate–methanol (92 : 8). Both isomers are detected at 262 nm.

An HPLC method for ceftibuten isomers is also developed for plasma and urine samples. Samples are deproteinized with ethanol and injected into an ODS column with a mobile phase composed of PIC A (tetrabutylammoniumphosphate)–acetonitrile–methanol (50 : 6 : 3). Both isomers are detected at 256 nm with a detection limit of $1 \mu\text{g mL}^{-1}$ for each isomer.

Cephalexin

Cephalexin epimers are separated with an ODS column using a mobile phase of 0.1 mol L^{-1} phosphate buffer (pH 3.5)–methanol (95 : 5). The epimers are detected at 254 nm. The two epimers are separated to the baseline with the L-epimer being eluted prior to the D-epimer.

Cephalexin epimers in serum and urine are analysed using a TSK-gel ODS-80 TM column after deproteinization with methanol. Mobile phase compositions are 10 mmol L^{-1} ammonium acetate–methanol (4 : 1) for determination of the D-epimer, and 10 mmol L^{-1} phosphate buffer (pH 3.0)–methanol (9 : 1) containing 10 mmol L^{-1} ammonium acetate and 10 mmol L^{-1} pentanesulfonic acid for determination of the L-epimer. The epimers are detected at 260 nm.

Other β -Lactams

Epimers of phenethicillin (PEPC, **Figure 3**, structure 11), propicillin (PPPC, **Figure 3**, structure 12) and clometocillin are analysed with a Zorbax C₈ column. The mobile phase is composed of methanol–water–5% 0.2 mol L⁻¹ phosphate buffer (pH 7.0) and the epimers are detected at 254 nm. Ratios of methanol in the mobile phase are 37.5, 45 and 50% for PEPC, PPPC and clometocillin, respectively. Epimers are resolved close to the baseline, and the D-epimers elute faster than the corresponding L-epimers.

The same HPLC conditions can be used for the analysis of ampicillin, amoxicillin and azidocillin, except that the methanol content is varied between 10 and 40%. The L-epimer elutes faster for ampicillin, whereas the D-epimer elutes faster for amoxicillin and azidocillin. The less active epimers are not detected in the commercial preparations of these penicillins.

Epimers of PEPC and PPPC are also resolved with an ODS column. The mobile phase consists of 100 mmol L⁻¹ ammonium acetate–methanol (62 : 38 and 58 : 42 for PEPC and PPPC, respectively) with a UV detection at 220 nm. PEPC and PPPC epimers are baseline separated (**Figure 5**).

Bacampicillin and cefotiam hexetil are the prodrugs of ampicillin and cefotiam, respectively, which are commercially available as mixtures of two epimers due to chirality of the prodrug moiety. For separation of bacampicillin isomers, an ODS column is used with a mobile phase consisting of 20 mmol L⁻¹ ammonium acetate–methanol (45 : 55). The isomers are detected at 220 nm. For separation of the isomers of cefotiam hexetil, an ODS column is used with a mobile phase consisting of 50 mmol L⁻¹ phosphate buffer (pH 3.0)–acetonitrile (73 : 27). The isomers are detected at 262 nm. Baseline separation of the isomers of bacampicillin and cefotiam hexetil are observed.

Semisynthetic cephalosporins are extracted from biological fluids and chromatographed with an ODS column. Urine samples are merely centrifuged and diluted with distilled water. Serum samples are mixed with 0.4 mol L⁻¹ HCl and extracted with CHCl₃–*n*-pentanol (3 : 1). The organic phase is re-extracted into phosphate buffer (pH 7), which is injected into the HPLC. The mobile phase is 0.01 mol L⁻¹ acetate buffer (pH 4.8)–methanol (15 : 85) with detection wavelengths of 254, 245, 234, 275, 270, 240 and 240 nm for cefuroxime, cefoxitin, cefotaxime, cefazolin, cefamandole, cephalotin and cefoperazone, respectively.

Cephalosporins in serum are also analysed with an octyl column using a mobile phase of methanol–12.5 mmol L⁻¹ phosphate buffer (pH 2.6, 1 : 4). Cefaclor, cefadroxil, cefixime, cephalixin and cephadrine are simultaneously analysed and detected at 240 nm. The detection limits are 0.1 μ g mL⁻¹ for cefixime and 1.0 μ g mL⁻¹ for other cephalosporins. Serum is deproteinized with acetonitrile.

Cephalosporins with a tetrazole ring are analysed from plasma with an ODS column using a mobile phase consisting of 0.05 mol L⁻¹ phosphate buffer (pH 6.6)–methanol with ratios of 3 : 1 and 2 : 1 for cefamandole and cefoperazone, respectively. For cefotiam and cefmetazole, a mixture of phosphate buffer–tetrahydrofuran (20 : 1) is used as a mobile phase. Cephalosporins are detected at 254 nm with a limit of detection of 1 μ g mL⁻¹ for all cephalosporins.

In order to increase sensitivity, ampicillin, amoxicillin, cephalixin and cephadrine in plasma are assayed after formation of fluorescent degradation products. Plasma is deproteinized with 10% trichloroacetic acid and the supernatant is heated under various conditions to form degradation products. The degradation products are extracted with an organic solvent and injected into a Nucleosil C₁₈ column at

Figure 5 Chromatogram of phenethicillin. One hundred microlitres of an aqueous solution of phenethicillin (22 μ g mL⁻¹) was directly injected onto HPLC.

Table 1 HPLC conditions for β -lactams

β -Lactam	Stationary phase	Mobile phase	Detection
Benzylpenicillin	ODS	Methanol–0.05 mol L ⁻¹ ammonium carbonate (1 : 3)	UV (254 nm)
Benzylpenicillin	ODS	Phosphate buffer (pH 6.0)–acetonitrile (4 : 1)	UV (225 nm)
Cefsulodin	ODS	16.8 mmol L ⁻¹ dibasic ammonium phosphate–acetic acid–methanol (100 : 1.68 : 5.98) containing 5 mmol L ⁻¹ triethylamine	UV (260 nm)
Cefsulodin	ODS	Aqueous solution (containing 38.8 mmol L ⁻¹ ammonium acetate, 0.292 mmol L ⁻¹ dibasic ammonium phosphate and 9.363 mmol L ⁻¹ triethylamine)–acetonitrile–methanol–dimethylformamide–acetic acid (1000 : 7.06 : 1.05 : 1.31 : 0.30)	UV (260 nm)
Moxalactam	ODS	Methanol–0.05 mol L ⁻¹ monobasic potassium phosphate (5 : 95) adjusted to pH 6.5	UV (254 nm)
Moxalactam	ODS	Methanol–0.005 mol L ⁻¹ tetra- <i>n</i> -butylammonium phosphate (1 : 3) adjusted to pH 6.0	UV (254 nm)
Moxalactam	ODS	0.1 mol L ⁻¹ Ammonium acetate–acetonitrile (95 : 5) adjusted to pH 6.5	UV (270 nm)
Moxalactam	ODS	0.1 mol L ⁻¹ Sodium phosphate–methanol (84 : 16) adjusted to pH 3.2	UV (254 nm)
Temocillin	ODS	Methanol–0.1 mol L ⁻¹ phosphate buffer (pH 7.0, 1 : 9)	UV (230 nm)
Temocillin	Octyl silane	Methanol–0.1 mol L ⁻¹ phosphate buffer (pH 7.0, 16 : 84)	UV (230 nm)
7-Ureidoacetamido cephalosporins	ODS	0.01 mol L ⁻¹ Diammonium hydrogen phosphate containing 5–20% methanol	UV (254 nm)

55°C. The mobile phase consists of methanol–water (3 : 2) with a fluorescent detection at 345 nm (excitation) and 420 nm (emission) for ampicillin, cephalexin and cephadrine. For amoxicillin, the mobile phase is methanol–water (55 : 45) with a fluorescent detection at 355 nm (excitation) and 435 nm (emission). Detection limits are 0.5 ng mL⁻¹ for ampicillin, 2 ng mL⁻¹ for cephalexin and 10 ng mL⁻¹ for amoxicillin and cephadrine. For sensitive determination of β -lactams, pre-column derivatization with imidazole–metal salt reagent or formaldehyde, or post-column derivatization with *o*-phthalaldehyde or fluorecamine may be applied.

HPLC conditions for several other β -lactams are summarized in Table 1. Epimers of these β -lactams are separated using the conditions listed in Table 1, except for benzylpenicillin.

Fluoroquinolones

Among fluoroquinolone antibiotics, lomefloxacin, ofloxacin and temafloxacin are used clinically as the racemates (see Figure 6, structures 19, 20 and 21, respectively). Therefore, enantiospecific HPLC methods are described below for these fluoroquinolones. Non-chiral HPLC conditions for the chiral as well as other non-chiral fluoroquinolones are summarized in Table 2. Detection limits listed in Table 2 are mostly those for plasma or serum analysis.

Lomefloxacin

Lomefloxacin enantiomers are extracted from plasma at pH 7 with a mixture of chloroform–isopentyl alcohol–diethyl ether (71.25 : 3.75 : 25) and derivatized with *S*-(+)-(1-naphthyl)ethylisocyanate to form diastereomers. Derivatized diastereomers are analysed with a Radial Pak normal-phase column using a mobile phase of hexane–chloroform–methanol (64.5 : 33 : 2.5). Diastereomers are detected fluorometrically at 280 and 470 nm for excitation and emission. The limit of accurate quantification is less than 10 ng mL⁻¹ for each enantiomer.

Ofloxacin

Serum and urine samples are diluted with 0.1 mol L⁻¹ phosphate buffer (pH 7.0) and extracted with dichloromethane. Ofloxacin enantiomers in the extract are reacted with L-leucinamide to form diastereomers. The diastereomers are extracted with 1 mol L⁻¹ HCl, and injected into an ODS column. The mobile phase is 0.2 mol L⁻¹ phosphoric acid (with the pH adjusted to 1.85 with tetraethylammonium hydroxide)–acetonitrile (4 : 1) with fluorescence detection at 298 nm excitation and 458 nm emission. The derivative of the *S*-(–)-enantiomer elutes prior to that of the *R*-(+)-enantiomer with baseline separation. Detection limits are 3 and 80 ng mL⁻¹ for plasma and urine, respectively.

Ofloxacin enantiomers are also analysed using a chiral stationary phase (bovine serum albumin

Figure 6 Chemical structures of lomefloxacin (19), ofloxacin (20) and temafloxacin (21).

covalently bonded to silica) without derivatization. Mobile phase is 0.2 mol L⁻¹ phosphate buffer (pH 8.0)–2-propanol (97 : 3). Enantiomers are detected fluorometrically at 298 nm excitation, 458 nm emission. Resolution and sensitivity are poorer than those for the above derivatization method.

For clinical use, ofloxacin has been changed to levofloxacin which is the pharmacologically active *S*-(–)-enantiomer.

Temafloxacin

Temafloxacin enantiomers in biological fluids are extracted with methylene chloride and analysed by two types of HPLC method with derivatization. For the first method, temafloxacin enantiomers are reacted with *S*-(–)-*N*-1-(2-naphthylsulfonyl)-2-pyrrolidine carbonylchloride to form diastereomers, which are injected into a silica gel column. The mobile phase is hexane–methyl acetate–methanol–ammonia water (150 : 100 : 10 : 1) with UV detection at 280 nm. The detection limit is 5 ng mL⁻¹ for each diastereomer with a separation coefficient of 1.05.

For the second method, temafloxacin is reacted with acetic anhydride to form acetylated temafloxacin followed by reaction with isobutylchloroformate to form carbonylamidated derivatives. These double-derivatized temafloxacin enantiomers are analysed with an ovomucoid conjugated silica gel column using a mobile phase of 0.02 mol L⁻¹ phosphate buffer (pH 7.0)–acetonitrile (92 : 8). The enantiomers are detected at 280 nm. The detection limit is 5 ng mL⁻¹ for each enantiomer with a separation coefficient of 1.50, indicating a better resolution by the second method.

Sulfonamides

Various sulfonamides are analysed with an ODS column using a mobile phase composed of acetic acid–triethylamine–water–acetonitrile–methanol (0.4 : 0.2 : 710 : 100 : 100) and detection at 254 nm. Sulfonamides in formulations are extracted or dissolved using dimethylformamide, methanol or the mobile phase.

Sulfonamides in body fluids are analysed with an ODS column using a mobile phase consisting of acetonitrile–water (1 : 9, changing to 9 : 1 in 10 min). Detection is either UV at 254 nm or with a mass spectrometer. Sulfonamides are extracted with hexane–dichloromethane–ether (1 : 1 : 1) at pH 3.0–3.2.

Sulfamethoxazole

Sulfamethoxazole and its acetylated metabolites in body fluids are analysed with an ODS column using a mobile phase consisting of methanol–1% acetic acid (1 : 4, pH 2.9). Sulfamethoxazole and the metabolites are detected at 230 nm with a detection limit of less than 1 µg mL⁻¹. Plasma is extracted with ethyl acetate, and urine is deproteinized with acetonitrile.

Sulfamethoxazole in body fluids are also analysed with an ODS column using a mobile phase consisting of 0.067 mol L⁻¹ phosphate buffer (pH 6.7)–methanol (5 : 1). Sulfamethoxazole is detected at 260 nm with a detection limit of 0.5 µg mL⁻¹.

Sulfasalazine

Sulfasalazine is decomposed in the colon to generate two biologically active drugs, i.e. sulfapyridine and 5-aminosalicylic acid. Sulfasalazine in commercial preparations is analysed with an ODS column using a mobile phase consisting of 10–15% 2-propanol in 0.01 mol L⁻¹ phosphate buffer (pH 7.7), and detected at 254 nm. A silica column is also used for analysis of sulfasalazine and its degradation products in commercial preparations with a mobile phase of chloroform–acetonitrile–*n*-butanol (4 : 1 : 1).

Table 2 Non-stereospecific HPLC conditions for chiral as well as non-chiral fluoroquinolones

Fluoroquinolone	Stationary phase	Mobile phase	Detection ¹	Detection limit
Enoxacin	ODS	30% Methanol in an aqueous solution of 0.05 mol L ⁻¹ potassium dihydrogen phosphate and 2% acetic acid	UV (265 nm)	3 pmol
Ciprofloxacin	ODS	An aqueous solution of 18 mmol L ⁻¹ potassium dihydrogen phosphate and 0.13 mmol L ⁻¹ heptane sulfonic acid-methanol-phosphoric acid (7 : 3 : 0.01)	Fluorescence (ex. 278 nm, em. 475 nm)	200 ng mL ⁻¹
Lomefloxacin	ODS	An aqueous solution of 0.2% sodium acetate trihydrate, 0.2% citric acid monohydrate and 0.1% triethylamine (pH 4.8)-acetonitrile (80 : 23)	Fluorescence (ex. 280 nm, em. 430 nm)	50 ng mL ⁻¹
Nalidixic acid	ODS	Water-methanol-cetrimonium bromide (50 : 50 : 0.12)	(UV 313 nm)	1 µg mL ⁻¹
Nalidixic acid	Amino-cyano	Methanol-0.1 mol L ⁻¹ citrate buffer (pH 3, 95 : 15)	(UV 254 nm)	0.1 µg mL ⁻¹
Norfloxacin	Anion-exchange	0.05 mol L ⁻¹ phosphate buffer (pH 7)-acetonitrile (4 : 1)	(UV 273 nm)	0.1 µg mL ⁻¹
Norfloxacin	ODS	Acetonitrile-0.01 mol L ⁻¹ phosphate buffer (pH 2.5) containing 1 mmol L ⁻¹ triethylamine (11 : 89)	(UV 279 nm)	20 ng mL ⁻¹
Ofloxacin	ODS	0.5% Sodium acetate (pH 2.5)-acetonitrile (87 : 13)	(UV 300 nm)	100 ng g ⁻¹ tissue
Ofloxacin	ODS	Tetrahydrofuran-0.06 mol L ⁻¹ phosphate buffer (pH 2.6) containing 3% triethylamine (5.5 : 94.5)	Fluorescence (ex. 282 nm, em. 450 nm)	20 ng mL ⁻¹
Pefloxacin	ODS	An aqueous solution of 0.2% sodium acetate, 0.2% citric acid and 0.1% triethylamine-acetonitrile (86 : 14)	Fluorescence (ex. 330 nm, em. 440 nm)	50 ng mL ⁻¹
Sparfloxacin	ODS	5% Acetic acid-acetonitrile-methanol (70 : 15 : 15)	UV 364 nm	5 ng mL ⁻¹
Temafloxacin	ODS	53% Acetonitrile in an aqueous solution of 40 mmol L ⁻¹ phosphoric acid, 10 mmol L ⁻¹ sodium dihydrogen phosphate, 0.2% sodium dodecyl sulfate and 5 mmol L ⁻¹ <i>N</i> -acetylhydroxamic acid	Fluorescence (ex. 280 nm, em. 389 nm)	10 ng mL ⁻¹
Temafloxacin	ODS	19% Acetonitrile in an aqueous solution of 5 mmol L ⁻¹ tetrabutylammonium bromide, 10 mmol L ⁻¹ sodium hydrogen phosphate	Fluorescence (ex. 275 nm, em. 450 nm)	10 ng mL ⁻¹
Fleroxacin	ODS	10% Acetonitrile in an aqueous solution of 5 mmol L ⁻¹ tetrabutylammonium bromide, 10 mmol L ⁻¹ sodium hydrogen phosphate	Fluorescence (ex. 277 nm, em. 445 nm)	2.5 ng mL ⁻¹
Fleroxacin	ODS	Phosphate buffer (pH 3)-acetonitrile-methanol (85 : 7.5 : 7.5) containing tetrabutylammonium hydroxide and triethylamine	Fluorescence (ex. 290 nm, em. 470 nm)	5 ng mL ⁻¹

¹ex., excitation; em., emission.

Sulfasalazine in plasma is extracted with isoamyl acetate and analysed with an ODS column using a mobile phase of 0.01 mol L⁻¹ phosphate buffer (pH 7.7)-acetonitrile (83 : 17). Sulfasalazine is detected at 365 nm with a limit of detection of 5 ng.

Sulfasalazine, sulfapyridine, 5-aminosalicylate and their metabolites in plasma are analysed with

a methylsilane column using a mobile phase of methanol-0.05 mol L⁻¹ phosphate buffer (pH 7.4) containing 0.1% tetrabutylammonium hydrogen sulfate (22.5 : 77.5). The eluants are monitored fluorometrically at 320 nm excitation, 389 nm emission, with a detection limit of 0.5 µg mL⁻¹. Plasma is deproteinized with methanol.

Tetracyclines

Various tetracyclines are analysed with an octyl column using a mobile phase of methanol–acetonitrile–0.01 mol L⁻¹ aqueous oxalic acid solution (pH adjusted to 2.0 with 28% aqueous ammonia, 1 : 1.5 : 5) and detection at 360 nm.

Tetracycline (TC), chlortetracycline (CTC), doxycycline, minocycline, oxytetracycline (OTC), impurities of these tetracyclines including 4-epitetracycline, anhydrotetracycline and 4-epianhydrotetracycline (a nephrotoxic degradation product) are resolved with an ODS column using a gradient system (see Figure 7 for chemical structures). The mobile phase is an aqueous solution of 1 mmol L⁻¹ tetraammonium ethylenediamine tetraacetate and 50 mmol L⁻¹ diethanolamine (pH adjusted to 7.3 with 85% phosphoric acid) containing 2–10% isopropanol. Tetracyclines are detected at 254 nm. Impurities of tetracycline are also analysed with an ODS column using a mobile phase consisting of methanol–acetonitrile–0.2 mol L⁻¹ aqueous oxalic acid solution (pH adjusted to 2.0 with 28% aqueous ammonia, 1 : 1 : 3.5). Tetracycline and impurities are detected at 400 nm.

TC, CTC and OTC in plasma and urine are analysed with an ODS column using a mobile phase consisting of 0.01 mol L⁻¹ phosphate buffer (pH 2.4)–acetonitrile (7 : 3 or 6 : 4). Tetracyclines are detected at 355 nm with a detection limit of 1 µg mL⁻¹. Extraction of tetracyclines from biological fluids into

ethyl acetate is improved by formation of phenylbutazone–tetracycline ion-pairs.

Other Antibiotics: Azole Antifungals

Itraconazole and its active metabolite (hydroxyitraconazole) in serum are analysed with a Lichrospher RP8 column using a mobile phase of acetonitrile–water (62 : 38) containing 0.05% diethylamine. The pH of the mobile phase is adjusted to 6.0 with 30% acetic acid. Itraconazole and hydroxyitraconazole are detected at 258 nm with detection limits of 10 and 7 ng mL⁻¹, respectively. Serum is extracted with heptane–isoamyl–alcohol (9 : 1).

Itraconazole and hydroxyitraconazole in plasma and tissue are also analysed with an ODS column using a mobile phase of water–acetonitrile–diethylamine (42 : 58 : 0.05). The pH of the mobile phase is adjusted to 2.45 with 85% phosphoric acid. Itraconazole and hydroxyitraconazole are detected fluorometrically at 260 nm excitation and 365 nm emission. Detection limits of itraconazole are 5 ng mg⁻¹ and 5 ng mL⁻¹ for tissue biopsy and plasma, respectively. Itraconazole in tissue or plasma is extracted with methanol.

Fluconazole in plasma is analysed with an octyl column using a mobile phase of water–acetonitrile (72 : 28). Fluconazole is detected at 260 nm with a detection limit of 0.4 µg mL⁻¹. Plasma is deproteinized with acetonitrile.

Miconazole in plasma is analysed with an ODS column using a mobile phase of methanol–acetonitrile–0.01 mol L⁻¹ phosphate buffer (pH 7.0, 36 : 36 : 28). Miconazole is detected at 230 nm with a detection limit of 5 ng mL⁻¹. Plasma is treated with an octadecyl solid-phase extraction column prior to HPLC analysis.

Econazole in serum is determined with an ODS column using a mobile phase of 0.01 mol L⁻¹ potassium dihydrogen phosphate–methanol (3 : 7), with the pH being adjusted to 4.5. Econazole is detected at 220 nm with a detection limit of 40 ng mL⁻¹.

Sulconazole in plasma is analysed with an ODS column using a mobile phase of acetonitrile–0.01 mol L⁻¹ phosphate buffer (pH 8, 66 : 34). Sulconazole is detected at 229 nm with a detection limit of less than 0.5 µg mL⁻¹.

Some of the azole antifungals are used clinically as the racemates, and the enantio-specific HPLC conditions with a chiral stationary phase, tris(chloromethylphenylcarbamate)s of cellulose, are reported. The mobile phase is *n*-hexane–2-propanol (85 : 15) for separation of enantiomers of enilconazole, econazole, miconazole and ornidazole, and *n*-hexane–2-propanol (9 : 1) for bifonazole enantiomers. A similar

Figure 7 Chemical structures of tetracycline (22), chlortetracycline (23), doxycycline (24), minocycline (25) and oxytetracycline (26).

type of cellulosic chiral stationary phase (Chiralcel-OD) with a mobile phase of *n*-hexane-2-propanol (9 : 1) is used for separation of sulconazole enantiomers.

Conclusion

Since there is an enormous volume of information on the separation of antibiotics in the literature, readers should be able to find HPLC conditions for almost any antibiotic of interest. Readers are also encouraged to consult the official compendia for analysis of bulk or formulated drugs. For analysis of biological samples, the samples may be directly injected with a column switching technique instead of employing liquid-liquid or solid-phase extraction. For sensitive detection, drugs may be subjected to pre- or post-column derivatization, especially with a fluorescent chromophore. Diastereomeric derivatization is useful for analysis of chiral drugs. Mass spectrometric (MS) detection is another way to increase sensitivity. Indeed, cephem and macrolide antibiotics are analysed with HPLC-MS to detect minute amount of drugs. For cephem antibiotics, capillary HPLC has been coupled with mass spectrometric detection.

Supercritical Fluid Chromatography

Introduction

The analysis of antibiotics is of primary importance for drug monitoring in pharmacokinetic and health studies, as well as for the quality control of drug production and of numerous food products. As a consequence, the demand for new methods of determination of antibiotics of very different types is continuously increasing. The main methods employed for these analyses include immunoassays and chromatography, as well as various chemical techniques. Among the chromatographic methods, high performance

liquid chromatography (HPLC) is the most commonly used, followed by thin-layer chromatography and gas chromatography (GC), while supercritical fluid chromatography (SFC) is still being introduced to this area of application.

In SFC the mobile phase is a fluid subjected to pressures and temperatures near or above the critical point of that fluid, to enhance and control the mobile-phase solvating power. This fact determines that the mobile-phase properties (e.g. diffusivity, density, viscosity) are intermediate between those of gases and liquids and can be varied and controlled by small changes in the pressure or temperature of the systems. The most common fluid used in SFC is carbon dioxide, which has a critical temperature of 31°C, allowing the separation of thermally labile compounds under mild conditions. In general, antibiotics are compounds with intermediate to high polarity, while

supercritical carbon dioxide only has an adequate solvating power for nonpolar compounds. For that reason, the elution of more polar solutes requires the addition of a more polar organic solvent (for example, 5–30% methanol), the so-called modifier, that increases the polarity of the mobile phase and has a solvating effect on silica-based packed columns. With this technique it is possible to separate antibiotics in complex samples at lower temperatures than GC and in shorter times than liquid chromatography. The use of low concentrations of additives in the modifier (for example, 0.1% trifluoroacetic acid and/or 0.1% triethylamine) is also used to control the separation conditions to an even greater extent, especially retention, peak shape and enantioselectivity.

SFC can be divided into two categories based on column type – open tubular and packed – with differences in selectivity, detection and need for modifier addition to the carbon dioxide characterizing the two types. Both types have been employed in the separation of drugs in very different samples. Separations of antibiotics and related compounds are best performed using packed columns, although there are some applications that do well on open tubular columns. Packed columns can be used with UV detection and a wide range of packing materials, from pure silica, to phenyl, diol, amino, octadecyl-modified silica or chiral materials such as cyclodextrins, derivatized cellulose or amylose. For these silica-based columns, the peak symmetry is improved and the retention times of the antibiotics are shortened when a modifier is added to the carbon dioxide, due to the solvating effect on the free silanol groups of the silica (cf. end-capping in HPLC). In general, the separation of antibiotics in SFC is affected by the number, location, nature and conformation of the individual functional groups, which can define the need or not, as the case may be, of a modifier and additive. Nevertheless, the determination of antibiotics by SFC is not so straightforward as other pharmaceutical separations and until now it has not been thoroughly developed.

The area that has been developed the most is probably the chiral separation of antibiotics and related compounds, where the combination of a temperature that is milder and more selective than GC and an efficiency better than HPLC results in enhanced resolution, which is especially valuable.

Another area where supercritical fluids have a niche is the monitoring of food products for antibiotic residues. This area is of increasing importance due to the concern for the effect on human health that abuse of these drugs can have. In this case, the main advantage of supercritical fluids is in the sample preparation from these complex matrices, when supercritical fluid extraction coupled to SFC can be used.

SFC versus HPLC for the Determination of Antibiotics and Related Drugs

The main problem posed in the separation of antibiotics is their broad range of structures that covers almost the whole range of organic chemistry. This includes carbohydrate, macrocyclic lactones, quinones, peptides and heterocyclic compounds, although antibiotics in general are relatively polar, nonvolatile and thermally labile drugs. For that reason, liquid chromatography has increasingly been chosen as the method of analysis, and SFC is gaining greater acceptance with the extended use of packed columns combined with organic modifiers and additives that allow the separation of the more polar solutes.

GC commonly provides the highest resolution in the shortest analysis time, but it also requires high temperatures and often derivatization of the drugs. HPLC methods have lower resolution and longer analysis times. The SFC technique can provide the same resolution as GC and short run times, but with the added benefit that it does not need high temperatures (Figure 1). Typical temperatures are as low as 50–80°C in packed-column SFC.

The packed columns used for SFC of polar drugs are similar to the columns used in HPLC, although back-pressure is not a problem in SFC, allowing columns to be coupled in series to achieve high resolution systems, even for polar analytes. When it comes to detection, the commonest systems for antibiotics determination are UV (Figure 2), or mass spectrometry (MS). In comparing packed-column SFC and LC, the ultraviolet detector can be operated at lower wavelengths in SFC, because of the lack of background absorbance from the solvent and the mass spectrometric ionization techniques work best with volatile mobile phases also favouring SFC (Table 1).

Characteristics of the Separation of Antibiotics using Supercritical Fluids

The main properties of SFC which significantly affect antibiotic separation are related to the high solvating power of supercritical fluids and their low viscosity, which yields high resolution power and throughput. This fact has two main consequences on this type of separation. Firstly, as already pointed out above, compounds like antibiotics can be analysed at lower temperatures than in gas chromatography, and in shorter times than in liquid chromatography, as a result of good solvating capacity. Secondly, SFC is able to resolve complex mixtures of not very volatile compounds, allowing the direct injection of samples

Figure 1 Structures of eight sulfonamides determined by SFC (see chromatogram shown in Figure 2).

that contain antibiotics with little or no sample pre-treatment.

Some antibiotics may be degraded or lost during exposure to light, heat or extreme values of pH. In SFC, all these factors are avoided, providing separation under mild conditions that preserves the integrity of the sample.

Antibiotic determination presents some difficulties due to the complexity of the sample matrix and the relatively low concentration of the antibiotics in these samples. The whole procedure, including extraction and fractionation, is not only time-consuming and prone to error, but may degrade labile antibiotics and create artefacts. Consequently, new approaches have been developed in the last few years that avoid several or all of these questionable sample preparation steps by using multidimensional systems or even direct injection in SFC.

The analysis of antibiotics in human serum has been performed with both open tubular and packed-column SFC. With open tubular columns, it is possible to determine the antibiotic content with a simple liquid-liquid extraction. The use of a flame ionization detector has, however, not demonstrated satisfactory detection limits to date. Better results have been obtained with SFC and mass spectrometric detection, which thus provides a very useful method for the determination of low levels of impurities in macrolide

antibiotics, and presents an alternative approach to several LC-MS methods.

Online SFE-SFC for the Analysis of Antibiotics

Online supercritical fluid extraction (SFE)-SFC can be used for the analysis of antibiotics in complex samples, resulting in time savings and less exposure to organic solvents. Multidimensional systems take advantage of two orthogonal separation techniques with complementary characteristics, for example one extraction and one chromatographic step, where the first step is aimed at producing a clean and undiluted sample containing the compounds of interest, and the second step provides a high resolution separation of the target analytes.

The main advantages of these online systems is that a fast and automatic sample preparation reduces or avoids the errors of the manual steps. Also, solvent consumption is less, which reduces toxic hazards and disposal costs. As is often the case in chromatography, the largest source of error in the quantitative analysis of antibiotics and the most time-consuming steps occur in the sample preparation and extraction stages.

Supercritical fluid techniques have a number of advantages for use in multidimensional chromatographic

Figure 2 Chromatogram obtained from SFC of a mixture of sulfonamides with UV (wavelength 270 nm). Peak identification: A, sulfadoxine; B, sulfamethazine; C, sulfamerazine; D, sulfadimethoxine; E, sulfadiazine; F, sulfaquinoxaline; G, sulfachlorpyridazine; H, sulfathiazole. Chromatographic conditions: column packed with 5 μm particle amino-bonded Spherisorb (100×4.6 mm i.d.), column temperature 90°C , CO_2 flow rate of 4 mL min^{-1} , pressure 361 bar. Mobile phase was CO_2 modified initially with 15% methanol and after 4 min with 25% methanol. Reproduced with permission from Perkins JR, Games DE, Startin JR and Gilbert JJ (1991) Analysis of sulfonamides using supercritical fluid chromatography and supercritical fluid chromatography-mass spectrometry. *Journal of Chromatography* 540: 239.

systems. The commonest multidimensional system, LC-GC, is limited to the determination of thermally stable and volatile solutes, while SFC can substitute the first fractionation step, as well as the second step of high resolution chromatography. In the case of SFE-SFC, the transfer is performed without changes in the mobile phase, which minimizes losses of analytes and reduces technical complexity

Analysis of Aqueous Matrices

Recently, new methods for the direct injection of water samples on to an adsorbent with solvent venting and online SFE-SFC of the target solutes have been developed.

In this procedure, the liquid sample is introduced in the SFE cell filled with a suitable adsorbent, which retains the solutes while the aqueous solvent is vented with an inert gas. The venting of the water improves the performances and flexibility of both the separation and the detection steps. After elimination of solvent, the analytes are extracted with supercritical carbon dioxide, and focused in a cryogenic trap, providing a solute enrichment before automatic online injection into the SFC column. In addition to its speed, this method provides a preconcentration step

for the analysis of trace levels of residues in biofluid samples and also allows class-selective extractions based on the tuneable polarity of the extracting agent, which thus represents an additional clean up stage and further reduces interface from the matrix.

This coupling has to date been applied to separations in open tubular columns of compounds in water samples, and may provide a breakthrough development for the future, with the use of packed capillary column SFC-MS for polar analytes. Although this method has not yet been applied to the determination of antibiotics, it could provide an automatic way of analysing drugs in biological fluids directly, i.e. with no separate extraction step.

Analysis of Antibiotic Residues in Food

Antibiotics have been used in animal feed for several decades to control infections and promote growth (Figure 3). Recently, increasing concern about antibiotic resistance has led to the prohibition of the use of some antibiotics for this purpose in several countries. Consequently, there is a growing interest in new and improved methods of analysis for antibiotics and their residues in food, and LC-MS is a common technique used to achieve this goal.

In solid and heterogeneous matrices such as food, sample preparation is the most time-consuming step in the routine determination of analytes in trace amounts, for instance, antibiotic residue levels. It remains the largest source of error in quantitative analytical methods. For this reason, the development of methods with less sample pretreatment requirements and with the possibility of automation is desirable.

For this application, SFC in combination with the universal flame ionization detector, or with highly sensitive mass spectrometric detection, shows a good balance between high resolution and good sample throughput, that can minimize the need for sample clean-up and be an optimal procedure in specific cases. An example of separation of veterinary antibiotics by SFC with UV detection prior to online SFC-MS can be seen in Figure 4.

An alternative approach is the online coupling of SFE and SFC for solid or semi-solid samples, allowing the extraction of the fraction of interest and the online transfer of the solutes from the liquid or solid matrix directly to the chromatograph, reducing solvent usage and the need for clean-up.

Chiral Separation of Antibiotics

The stereochemistry of an antibiotic is a prominent issue in the development, approval and clinical use of

Table 1 Determination of antibiotics by supercritical fluid chromatography

Column type	Sample	Comments	Detector	Reference
Packed (1 mm i.d., 5 µm particles) and open tubular (50 µm i.d.) columns	Sulfonamides and tetracyclines	100°C 8% Isopropanol as modifier	UV	Schmidt S, Blomberg, LG and Campbell ER (1988) <i>Chromatographia</i> 25: 775
Packed column 150 × 4.6 mm 5 µm particle amino silica	Erythromycin A Cephalosporins	65°C 2–8% Methanol as modifier	MS UV	Lane SJ (see Markides and Lee, 1988)

Different packed columns 250 × 4.6 mm 5 µm particles	Sulfonamides	50–100°C Great influence of temperature on resolution	UV	Combs MT, Ashraf-Khorassani M and Taylor LT (1997) <i>Journal of Chromatographic Science</i> 35: 176

This summary is not intended to be a comprehensive review of all antibiotic separations by SFC; it aims to provide general information on the main applications in this field.

these drugs. For the separation of enantiomers, SFC with chiral stationary phases is very convenient due to its high resolution and relatively low analysis temperature.

Chiral separations in SFC can be carried out using open tubular columns with immobilized cyclodextrins or, more recently, by packed columns with most of the same phases commonly used in LC, since the

**Figure 3** Structures of some veterinary antibiotics analysed by SFC.

Figure 4 Chromatograms obtained from SFC of a mixture of veterinary antibiotics with UV (A, wavelength 215 nm; B, wavelength 230 nm). Peak identification: A, levamisole; B, furazolidone; C, chloramphenicol; D, lincomycin. Chromatographic conditions: column packed with 5 μ m particle amino-bonded Spherisorb (100 \times 4.6 mm i.d.), column temperature 75°C, CO₂ flow rate of 4 mL min⁻¹, pressure 351 bar. Mobile phase was CO₂ modified with 15% methanol. Reproduced with permission from Perkins *et al.* (1991).

chiral selector is covalently bound to the packing material. The latter method frequently requires the addition of a modifier and is more common in the separation of drugs.

Several examples of the SFC of antibiotic enantiomers can be found in the literature, although the technique is not as commonly used as LC. Packed columns with chiral stationary phases are normally employed with carbon dioxide modified with methanol or ethanol as mobile phase, under supercritical or subcritical conditions (i.e. at room temperature). Further applications can be expected from the use of packed capillary columns for chiral separations, which may provide better resolution and shorter analysis times than the equivalent LC separation.

Future Developments

Current developments in new types of columns, equipment and detectors for SFC show that this technique has great potential for expansion and will achieve a broader use in the future with the advent of new instruments for packed capillary columns and adaptation of the routine use of MS-detectors, which

will be very valuable in the accurate determination of high and low concentration of antibiotics in samples where high resolution and mild conditions are imperative.

It is becoming more frequent to use solvents under subcritical conditions, which is blurring the boundary between SFC and LC – a fact that is already being used in chiral separations and will probably become more frequent in separations of antibiotics and related drugs.

Another probable source of improvement is the use of new detectors with higher sensitivity than UV and flame ionization detection and at the same time compatible with the use of modifiers in packed capillary column SFC. An example is the new amperometric detectors which avoid the problems observed in the quantitation of some drugs by SFC.

The development of new generations of commercial equipment for SFE-SFC and SFC-MS that are more user-friendly and robust than the present ones would also contribute to a wider use of this technology in quality control and research of pharmaceutical compounds.

History

Although recent advances in analytical methods have accelerated the study of these materials, the analysis and identification of ancient organic residues has a long history. An early example, in the 1920s, was the use of wet chemical techniques by the chemist Alfred Lucas to study organic material from pottery and mummified human remains from the tomb of Tutankhamun. Over the last 20 years or so, the analysis of organic residues has grown into a recognized field in its own right. Examples of organic residues include the debris associated with the remains of food and other natural products as a result of their manipulation in pottery containers (e.g. cooking of food), the balms in the wrappings of mummified bodies and traces of colouring dyes impregnated in ancient textiles. Given the amorphous character of organic residues, the most effective approach to their identification lies in their chemical composition. Characterization of organic residues generally relies upon the principles of chemotaxonomy, where the presence of a specific compound or distribution of compounds in an unknown sample is matched with its presence in a contemporary natural substance. The use of such molecular markers is not without its problems, since many compounds are widely distributed in a range of natural materials, and the composition of an ancient residue may have changed significantly during burial. In general, molecular markers belong to the compound class defined as the lipids, a heterogeneous group of molecules which includes fats and oils and molecules with common solubilities, such as the constituents of resins and waxes.

Early work in this field relied heavily on either thin-layer chromatography (TLC) or gas chromatography (GC) alone to characterize residues. Today, combined GC-mass spectrometry (GC-MS) and, to a lesser extent, high-performance liquid chromatography-MS (LC-MS) are demonstrating considerable value in identifying ancient organic matter. The wider availability of these techniques and, in particular, the introduction of GC-isotope ratio mass spectrometry (GC-IRMS), is contributing to more

specific identifications than was possible before. GC-IRMS allows the ratios of abundances of stable isotopes of elements such as carbon and nitrogen to be determined for individual compounds introduced via a gas chromatograph. Stable isotope ratios are of particular importance to studies of foodwebs due to the characteristic isotope signatures of plants utilizing different photosynthetic pathways. These distinctive ratios are passed along the food chain to herbivores and carnivores. The method requires very small samples and is being applied to trace organic residues in pottery vessels to establish their origin with a high degree of precision.

Methods

Analysis of archaeological material presents a number of challenges, including the small amount of sample available, the presence of complex molecular mixtures from more than one source, chemical alteration due to processing or degradation, and contamination. Furthermore, every sample is unique. These factors mitigate against simple interpretations of analytical results.

Recent developments in instrumental chromatographic techniques have enabled trace amounts of organic residues to be detected. Hence it is possible to analyse molecules surviving in an inorganic matrix such as pottery or soil, or surviving in morphological organic remains such as lipids in seeds or bone. Insoluble or polymeric fractions of residues that are not themselves volatile enough for conventional analysis can be broken up by pyrolysis, thereby allowing separation and identification of the fragments. Pyrolysis-GC-MS has been successfully applied to the recognition of biopolymers in fossil and recent higher plant resins, and to macromolecular debris remaining from the burning of food in archaeological pottery vessels.

Preparation of ancient lipids and natural products normally involves solvent washing of samples. Prefractionation of the lipid residue can be undertaken using microscale column chromatography or TLC. Prior to analysis, unhindered acid functionalities are derivatized by treatment with diazomethane. Trimethylsilylation using *N,O*-bis(trimethylsilyl) trifluoroacetamide (BSTFA) + 1% trimethylchlorosilane (TMCS) is used for the derivatization of hindered carboxyl groups and alcohols. In some cases an

internal standard is added to the sample to quantify yield.

GC remains a useful screening technique prior to GC-MS and can provide fingerprint chromatograms, whereby a complex set of peaks in a mixture can be matched to those in reference samples. Nevertheless, since molecular alteration is likely, this approach must be exercised with caution. Combined GC-MS provides valuable structural information on each of the components separated, and permits identification of molecular modification.

Applications

Residues Associated with Pottery

Fragments of broken and discarded pottery vessels are one of the most common classes of archaeological find. These sherds offer few immediate clues as to their original content and use – a significant point of enquiry in archaeology. During use, however, pottery vessels are known to accumulate residues of foods processed in them. If these residues survive long-term burial then they offer potential for determining artefact use. The residues occur as both charred or burnt deposits, which can be observed on the surface of the pottery, and as absorbed residues whereby organic components migrate into the pores of the vessel fabric. The porous microstructure of the fabric offers some protection to the residue from the effects of biodegradation and leaching during burial. The lipid constituents of these residues preserve rather well, and these can be extracted (by solvent washing of powdered sherd) from excavated sherds and analysed by GC and GC-MS.

A gas chromatogram from a typical degraded fat residue recovered from an archaeological sherd of Iron Age date (c. 100 BC) is shown in **Figure 1B**. The residue is rich in acylglycerols and free fatty acids and is typical of a partially hydrolysed lipid. This can be compared with the composition of fresh mammalian depot fat (**Figure 1A**), which is dominated by intact triacylglycerols. The monoacylglycerols, diacylglycerols and free fatty acids in the degraded fat result from the hydrolytic processes which begin as the pot is used (e.g. during boiling of food) and continue during burial. Furthermore, lipid residues are depleted in unsaturated fatty acids (such as oleic acid; C_{18:1}). This illustrates the problems in making simple comparisons between ancient lipids and fatty acid compositions of modern fats and oils.

Fractionation of the lipid to obtain minor constituents, such as sterols, can assist in determining a plant

or animal source (or indeed whether lipids from both are present). Odd and branched-chain fatty acids may also be present. These are characteristic components of bacteria. They are, however, also introduced into ruminant adipose tissue by bacteria in the rumen and migrate throughout the animal's body, contributing to all the tissues. The presence of appreciable levels of these components, both in the free state and as components of the acylglycerol fraction, supports the view that the predominant source of lipid in the example shown derives from a ruminant animal.

Identification of thermal degradation products may give clues to vessel use. The long chain ketones in **Figure 1** are formed by a high temperature reaction of fatty acids that is catalysed by the mineral matrix of the pottery fabric. Thus vessel use may be further understood by linking the molecular composition of the residues with exposure to high temperatures during formation, for example, during cooking. Recent research suggests that animal fats (such as adipose tissue, dairy products and fish/marine mammal oils) and plant tissues (notably the waxy compounds coating the surfaces of leaves) have the ability, under favourable burial conditions, to survive.

Pottery sherds may also exhibit the remains of organic surface treatments or sealants preserved as surface deposit. These are often resins, waxes or tars. GC analysis of one such deposit, a burnt surface residue on a neolithic potsherd, from Ergolding Fischergasse, Germany (mid 4th millennium BC), led to its identification as beeswax (**Figure 2**). The chromatograms shown compare wax ester distributions in fresh beeswax (*Apis mellifera*) with the fraction extracted from the surface deposit removed from the neolithic sherd. The principal wax esters in both samples are even-carbon-numbered aliphatic chains of saturated alcohols and fatty carboxylic acids with total carbon numbers in the range C₄₀ to C₅₀, with the C₄₆ wax ester the most abundant. The unsaturated wax esters present in the natural beeswax are absent from the neolithic residue. This is due to the deleterious effects of burial, during which the double bond is rendered susceptible to oxidation or reduction reactions. Natural beeswax also contains a considerable alkane component (in the range C₂₁–C₃₃), yet this was severely depleted in the archaeological sample, suggesting its combustion when the beeswax was burned. The sealing and water-repelling properties of beeswax suggest that it may have been used to seal the vessel to enable it to hold liquids. It is possible, however, that the vessel was used to store the beeswax for other uses. The identification of this commodity also implies the availability of honey to

Figure 1 Partial gas chromatograms showing the compositions of (A) fresh beef fat and (B) the lipid residue extracted from an Iron-Age cooking vessel from Easingwold, Yorkshire, UK. The peak identities were established by GC-MS and are as follows: F14–F18 denote saturated fatty carboxylic acids with 14–18 carbon atoms respectively; F18:1 denotes a monounsaturated fatty acid with 18 carbon atoms; M16 and M18 are monoacylglycerols with 16 and 18 fatty acyl carbon atoms respectively; K31, K33 and K35 are mid-chain ketones with 31, 33 and 35 carbon atoms respectively; D34 and D36 represent diacylglycerols with 34 and 36 fatty acyl carbon atoms respectively. T46–T54 are triacylglycerols with 46–54 fatty acyl carbon atoms respectively. * Internal standard.

Analytical conditions: gas chromatography was carried out on a Hewlett Packard 5890 series II gas chromatography, equipped with a flame ionization detector. Samples were introduced by on-column injection into a 60 cm \times 0.32 mm i.d. retention gap of deactivated polyimide-clad fused silica capillary tubing connected to the analytical column via a capillary connector. The carrier gas was helium at a constant flow of 1 mL min⁻¹. The temperature of the oven was programmed from 50 to 340°C at a rate of 10°C min⁻¹ following a 2-min isothermal hold at 50°C after injection, with the final temperature held for 8 min.

The combined GC-MS was performed using a Hewlett Packard 5972A quadrupole mass selective detector in conjunction with a Hewlett Packard 5890 series II gas chromatograph. Samples were introduced via a splitless injector at 340°C with a 3-min purge time. Helium carrier gas was at constant pressure of 10 psi. Mass spectra were recorded over a mass range of 50–700 μ m. The MSD interface temperature was 340°C, and the temperature was programmed from 50 to 340°C at a rate of 10°C min⁻¹ following a 2-min isothermal hold at 50°C after injection, with the final temperature held for 12 min.

In both cases, the analytical column was a polyimide-clad 12 m \times 0.22 mm i.d. fused silica capillary coated with BP1 stationary phase (immobilized poly(dimethylpolysiloxane), OV-1 equivalent, 0.1 μ m film thickness, SGE, UK).

neolithic communities in Europe. GC-MS has also been used to identify beeswax residues associated with medieval ceramics, and in lamps from late Minoan Crete where the wax was burned as a fuel.

Analysis of a large number of vessels from an archaeological site enables correlation between resi-

due type and pottery form and fabric, providing general assessments of use within assemblages.

Amorphous Residues and Adhesives

Amorphous organic substances can survive in other contexts, such as on stone tools, or as isolated

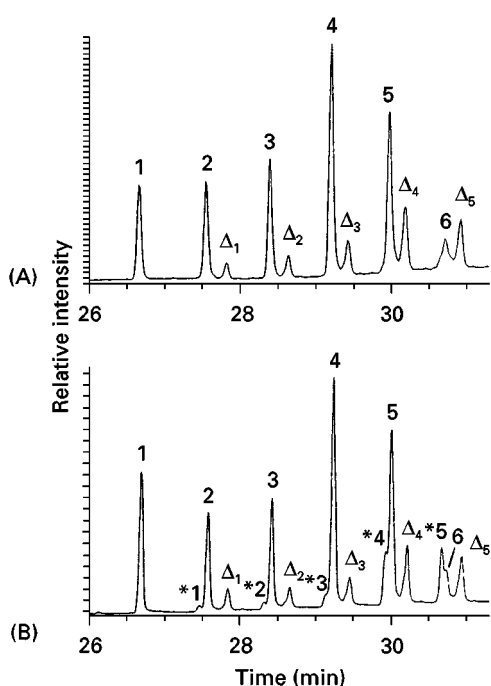

Figure 2 Partial gas chromatograms comparing the wax ester distribution in (A) Neolithic deposit on a potsherd from Ergolding Fischergasse, Germany with (B) authentic beeswax (*Apis mellifera*). Peak identities: 1–6 are wax esters in the range C_{40} (peak 1) to C_{50} (peak 6) comprising mostly hexadecanoic (palmitic) acid esterified with alcohols of increasing chain length (C_{24} to C_{34}). Peaks Δ_1 to Δ_5 represent co-elution of hydroxymonoester isomers and are seen in both samples. In contrast, peaks $*_1$ to $*_5$ are only present in the authentic sample and represent wax esters comprising an unsaturated (octadecanoyl) fatty acid moiety. Their absence in the ancient samples is not unexpected given the susceptibility of the double bond to oxidation or reduction reactions. Reproduced with permission from Heron C, Nemcek N, Bonfield KM *et al.* (1994). The chemistry of Neolithic beeswax. *Naturwissenschaften* 81: 266–269. Courtesy of Springer Verlag.

aggregates. An example is birch bark tar, which has been used as multipurpose natural product for at least 10 000 years, and its use continues to the present day in some parts of eastern and south-eastern Europe. The tar is obtained by heating fresh birch bark (*Betula* sp.) at temperatures of 250–350°C. Spectroscopic and chromatographic investigations of the material began during the 1960s, and a variety of techniques such as TLC, infrared and nuclear magnetic resonance (NMR) spectroscopy were used to identify birch bark tar on flint implements, lithics, ceramic and lumps of tar with human tooth impressions. More recent analysis has revealed that the tar was used to glue flint tips to arrows belonging to Ötzi – the ‘ice man’ discovered in the Tyrolean Alps in 1991. The tar has also been identified on potsherds, stone implements and worked bone from Ergolding Fischergasse (mid 4th millennium BC).

Many of the early analyses have recently been confirmed by GC-MS, including lumps with tooth impressions, interpreted as a very early form of chewing gum.

Figure 3 compares fresh birch bark tar with samples from the Mesolithic site of Star Carr (Yorkshire, UK). The triterpenoids of the outer bark of *Betula* sp. are derivatives of lup-20(29)-ene and, to a lesser extent, olean-2-enes. The triterpenoid composition is modified slightly by heating the bark and by some 9000 years of water-logged burial, but the identity and relative abundance of these biomarkers is sufficient to characterize the archaeological samples. Tars produced from other bark and wood samples have a very different molecular composition. For example, softwoods produce diterpenoid compounds and are easily distinguishable, while the barks and tars of other trees such as hazel, rowan and willow produce triterpenoids but with different carbon skeletons or relative abundance of the lup-20(29)-enes. Analysis by GC-MS enables identification of the molecular markers of the heating of the bark and post-depositional alteration (Figure 4).

Bitumen represents the fraction of sedimentary organic matter which is soluble in organic solvents. The liquid or semi-solid varieties of bitumen were widely used in the Near East and Middle East in antiquity, serving as a multipurpose glue and water-proofing material, a building mortar, medicinal agent and as one of the constituents of the organic preparations applied to mummified bodies in Ancient Egypt. Compounds consistent with a bituminous substance include saturated hydrocarbons which have linear (alkylated alkanes) or cyclic (steranes, terpanes) carbon skeletons. These molecules largely derive from microscopic plants deposited in the sediments as well as bacterial inputs. It has proved possible to identify molecular and isotopic characteristics of the bitumen, which enables archaeological finds to be assigned to a particular source of bitumen. At the site of Susa, Iraq (dating from the beginning of the 4th millennium BC), bitumen was deliberately mixed and heated with mineral elements, to produce a substance known as bitumen mastic – a product ideal for fashioning decorative objects by sculpture.

Understanding Archaeological Sites

In addition to extant residues, chromatographic analyses can be used to identify the remains of ancient human activities that are invisible to the archaeological excavator. Identification of β -stanols, which are faecal biomarkers, in soil samples from archaeological sites have enabled identification of specific site features such as cess pits. The approach may also be used on a large scale to look at issues of waste

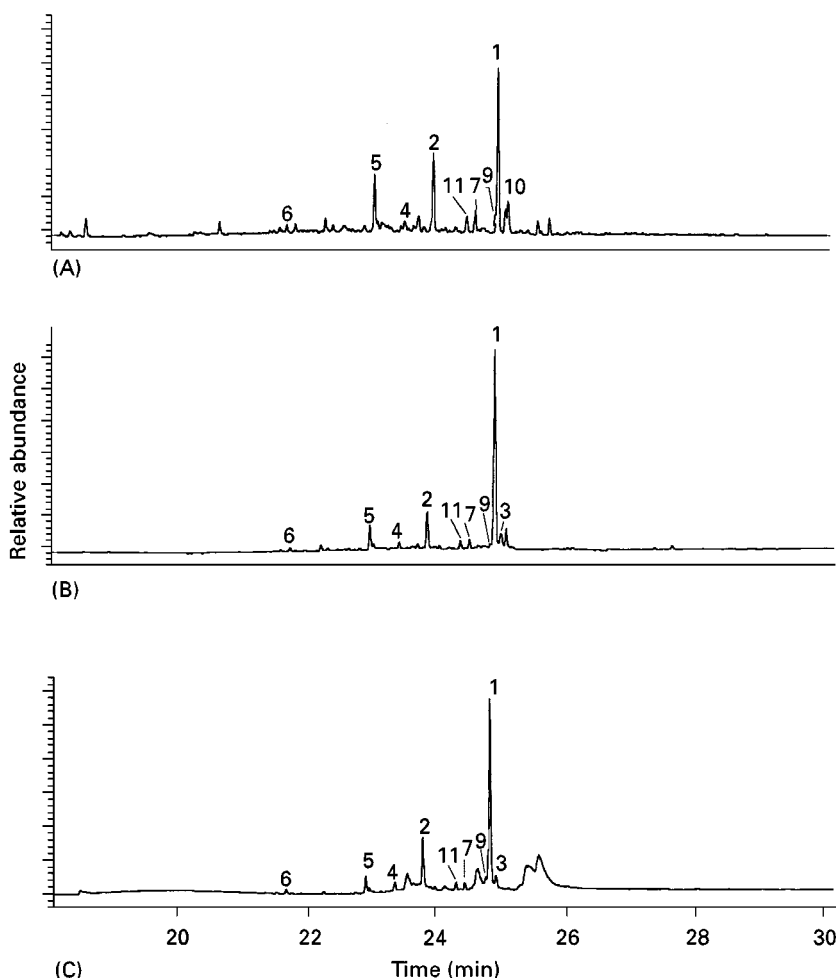

Figure 3 Partial gas chromatograms obtained by analysis of the solvent-soluble portions of samples of birch bark tar (*Betula pendula*) (peak identities were confirmed by GC-MS and are identified in Figure 4). (A) Birch bark tar prepared from fresh bark in the laboratory (350°C); (B) mesolithic sample from Star Carr ('resin cake'); (C) mesolithic sample from Star Carr (hafting glue). disposal and manuring patterns and early results suggest that the identification of specific sources of faecal matter may be possible.

Other Applications

These examples cover only a small part of the spectrum of archaeological approaches making use of chromatographic techniques. It should be emphasized that high performance liquid chromatography has been used not only for the separation of amino acids and peptides (for the purposes of dating, amino acid racemization studies and isotopic investigations), but also in the study of ancient wine residues in pottery containers from the Old World, the analysis of ancient dyes, the identification of alkaloids (such as caffeine and theobromine characteristic of cacao in Mayan archaeological ceramics from Mexico) and in

tracing alteration products of purine and pyrimidine bases in nucleic acid extracts of animal and plant remains.

Summary

Today, chromatography is embedded in the battery of analytical approaches used to interrogate the surviving materials and residues of past societies. The acceleration of research in biomolecular archaeology in the last decade can largely be attributed to the availability of increasingly sophisticated analytical techniques. GC-MS is becoming the routine approach for the characterization of lipids and natural products, and compound-specific carbon isotope determinations are proving their value in identifying the origin of residue components. Chromatographic

Peak number	R	R'	Compound name

Introduction

Analytical science plays a vital role in the conservation of our artistic heritage and chromatography is one of the most valuable techniques available to the conservation scientist.

In order to design the optimum safe conservation/restoration treatment plan, which takes account of the nature of the original materials used by the artist, conservators require a detailed knowledge of the materials used. The microscopic samples characteristic of work in this area are notoriously problematic to deal with and the sensitivity of the analytical technique is paramount.

The question why are some painted works in better condition than others of a similar age? is an important one for the conservator and specific information regarding the nature of the media used in such works may offer some insight as to why variations in the ageing characteristics of individual paintings occur.

Paint Media

Artists have traditionally used a diverse range of materials as binding media for their pigments: natural

oils, gums and proteinaceous materials such as egg, milk and collagen glues have all been incorporated into paint layers.

Oil painting was popular in northern Europe from before the 13th century and analytical evidence suggests that linseed oil was favoured, whilst in Italy, where oil painting was introduced in the 15th century, walnut oil was initially preferred. The oils most widely used in western European art are linseed, walnut and poppy, though the use of other oils, such as tung and safflower, has become more common in recent years.

Plant gums are commonly found as adhesives and binders. Gum arabic is primarily used as a painting medium, but others such as gum tragacanth (a medium for painting on linen) and cherry gum (which results in an enamel-like effect when mixed with egg or casein emulsions) are used less frequently. There is documentary evidence to suggest that gums have been employed as binding media and sizing materials for centuries: gum was used as a replacement for sun-dried oil as early as the 12th century.

Proteinaceous media include gelatine, milk and egg proteins. Animals and fish collagen glues are widely used as strong adhesives for wood, binders in the preparation of grounds, size for canvas, and pigment binders in decorative paints. Casein (a mixture of related phosphoproteins found in milk products), egg albumin (glair) and egg yolk (tempera) have traditionally found uses as pigment binders, temporary

varnishes and sealant over primers or grounds: in addition, casein provides one of the strongest natural adhesives known, much used by joiners and cabinet makers in the past.

The choice of binding medium is determined by a number of factors, predominantly the nature of the pigments being used, coupled with the effect desired by the artist, plus historical factors like location and the period of the piece. A variety of materials have enjoyed periodic popularity due to artistic trends and scientific progress.

Analysis of Paint Media

The analyses of oil-based media are well documented, but any information on the nature of other paint media has been obtained primarily via microscopic staining methods or crude solubility tests. Existing methods of analysis provide the basis for the separation of the general categories of binding media (oil, gum and protein) by qualitative means: for example, oil and protein layers can be distinguished by the differential staining of cross-sections, whilst colorimetric spot tests can be used for the identification of polysaccharide gums.

The applicability of these microanalytical techniques *in situ* can be advantageous, but the results can be misleading or inaccurate and for this reason these techniques are best used in conjunction with other analytical methods.

Such simple qualitative techniques, including paper and thin-layer chromatography (TLC), are adequate where merely the general category of binding medium is required, or where the material contains unique constituents (e.g. hydroxyproline in gelatine). However, only quantitative chromatographic techniques will enable differentiation between the similar binding media where they have no distinctive composition, such as in egg and milk proteins.

Gas Chromatography

Conservation scientists have routinely used gas chromatographic (GC) methods for the analysis of proteinaceous, oil and gum media for many years. The technique is highly sensitive – an important factor in the analysis of small samples – and a selection of derivatizing agents is available for use.

GC analysis of trimethylsilyl derivatives of amino acids in protein hydrolysate has been widely reported. The carboxyl group of an amino acid is easier to silylate than the amino group, which results in the formation of two products upon silylation: under mild conditions, the silyl ester is the major product

formed using hexamethyldisilazane as the silylating agent. Silylation of the amino group usually requires a stronger donor and silylation with either *N*-trimethylsilyldiethylamine or *N,O*-bis(trimethylsilyl)acetamide yields the silylamine-silyl ester.

Volatile butyl ester derivatives of amino acids found in the protein hydrolysate of binding media from paint layers and priming removed from 16th- and 18th-century easel and wall paintings have been used for GC analysis. Derivatization is achieved in two stages: the carboxyl functions are first converted into butyl esters by the addition of butanol (with dissolved hydrogen chloride), then the amino groups are acetylated with trifluoroacetic anhydride. The samples, dissolved in ethyl acetate, are separated on a temperature-programmed capillary column. Calculation of the relative peak areas of each amino acid revealed a distinctive profile for each of the binding media.

The existence of an amino acid profile was established for each of the protein media types, confirming their identity by the characteristic amino acid ratios seen for each. Proteinaceous material from the gesso, ground and paint layers of a selection of Italian works was hydrolysed under acid conditions, then deionized on a small ion exchange column. The samples were then successfully methylated (carboxyl function) and acetylated (amino function), yielding the highly volatile *N*-acetylmethyl esters of the amino acids, which were separated on a packed column. Results are shown in Table 1.

Loss of analytes is a problem associated with acid hydrolysis. The acid hydrolysis of proteinaceous samples in the presence of carbohydrates may lead to the elimination of amino acids as humins, which cause darkening of the hydrolysate and the formation of insoluble matter. A major contributory factor in the production of humins (a mixture of coloured compounds which resemble natural melanins) is the presence of tryptophan and amino sugars (e.g. galactosamine) or carbohydrates in the sample, which degrade during acid hydrolysis.

GC has been used to quantify the fatty acid content of eggs. The use of a tempera medium can be confirmed by the absence of azelate in the presence of both palmitate and stearate nondrying oils (i.e., oils which thicken but do not dry to a skin). Samples removed from aged paint films were saponified before methylation with diazomethane, then injected directly on to a wide-bore column. The presence of the methyl esters of saturated palmitic and stearic acids, with variable amounts of unsaturated oleic acid, was revealed. This method is also applicable for the analysis of oil-based media, the palmitate : stearate ratio proving the means of differentiation.

Reproduced from White (1984) with permission.

A mixed medium such as tempera contains both fatty acids and amino acids and GC has been employed to analyse both components simultaneously. Samples of mixed proteinaceous and oil media were hydrolysed under acid conditions, and derivatized to yield the volatile *N*-(*O*, *S*)-ethoxycarbonyl ethyl esters, which were then separated by capillary GC. This method has also been used for the analysis of amino acids alone.

Volatile ethyl chloroformate derivatives of amino acids in the hydrolysate of samples of proteinaceous media have been analysed to study the effects of pigments and ageing on the actual analysis/characterization of proteins from art objects, the results being interpreted via statistical methods.

GC is the method of choice for the analysis of natural gum media from works of art, though to date there has been relatively little work published in this area. An obvious problem associated with the use of many analytical techniques for this type of analysis is the insufficient sensitivity of the method for the microscopic samples available to the conservation scientist. However, progress has been made in the analysis of gum media by GC, often in conjunction with TLC.

Trimethylsilyl derivatives of sugars from the hydrolysed samples of surface coating taken from a wooden Egyptian sarcophagus (dating from the 21st dynasty) were analysed using a combination of GC and TLC, revealing the presence of gum tragacanth. The same

procedure was also employed for the analysis of the paint medium itself and disclosed the use of a mixture of gum tragacanth and honey.

Samples of media taken from Asian wall paintings were also found to contain polysaccharide material when analysed by GC and TLC. Gum sample hydrolysates were acetylated prior to analysis and characterization of the media, but the actual method of sample preparation was lengthy and tedious, requiring 12 h for hydrolysis and a further 5 h for derivatization.

Results obtained for the GC analysis of samples of gum from trees of the *Acacia* genus growing in the vicinity of the Tomb of Nefertari revealed that they were lacking in rhamnose, which usually indicates gum tragacanth, whilst the remainder of the sugar content matched that of gum arabic from other sources. When samples of media from paintings in the tomb were analysed by GC, the same sugar profile was observed: it was therefore concluded that the paint medium was in fact gum arabic.

Twilley's comprehensive analytical studies of natural gums and their artistic applications employed a variety of techniques, including the GC analysis of trimethylsilyl sugar derivatives. In addition, GC was used for the analysis of reference samples of aged ink, thus enabling the characterization of ink samples taken from a number of ancient manuscripts.

GC with a mass selective detector following a simple 'one-pot' hydrolysis and derivatization procedure was used for the characterization of a number of suspected gum media samples taken from the paint and ground layers of tempera works by William Blake. The results frequently indicated the presence of mixed gum media (typically comprising gums arabic, tragacanth and karaya) with the addition of cane sugar. Figure 1 shows the chromatograms of four

standard gum media samples, whilst Figure 2 shows the chromatograms obtained for samples of priming and paint media removed from two works by Blake, *Spiritual Form of Nelson Guiding Leviathan* (1805–9) and *Body of Christ Borne to the Tomb* (1799–1800).

GC has also facilitated the analysis of coatings, such as resins, waxes, lacquers and varnishes removed from works of art. Coatings are often applied

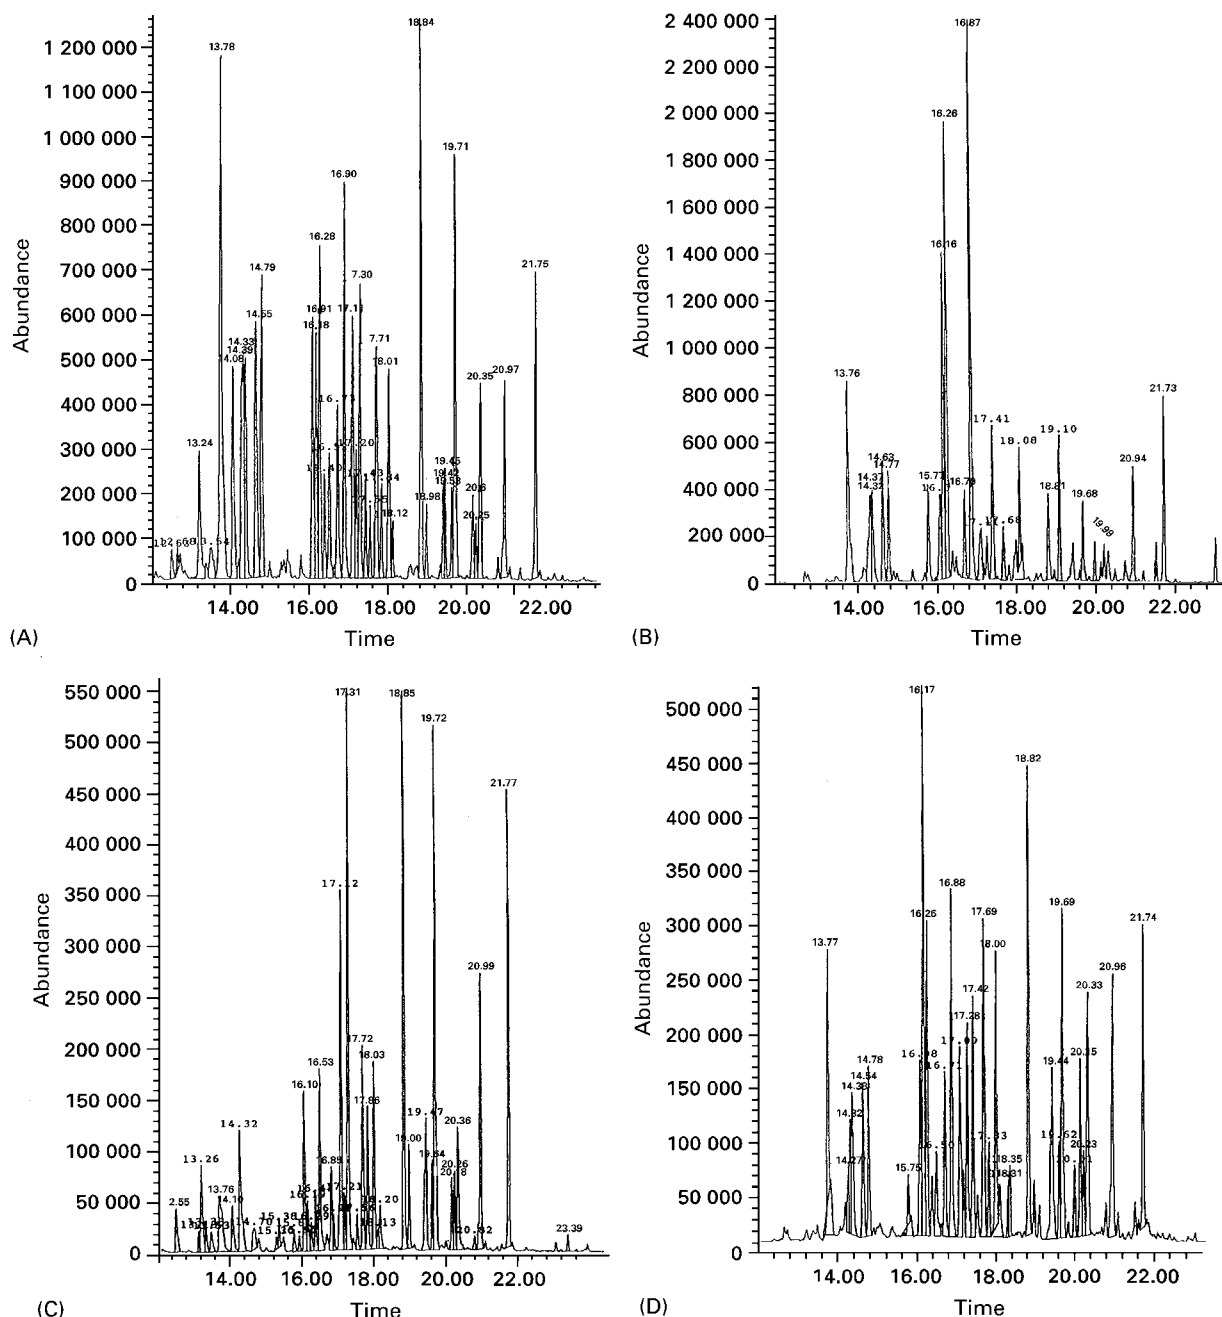

Figure 1 Chromatograms of four standard gum media samples: (A) gum arabic; (B) gum tragacanth; (C) karaya gum; (D) cherry gum.

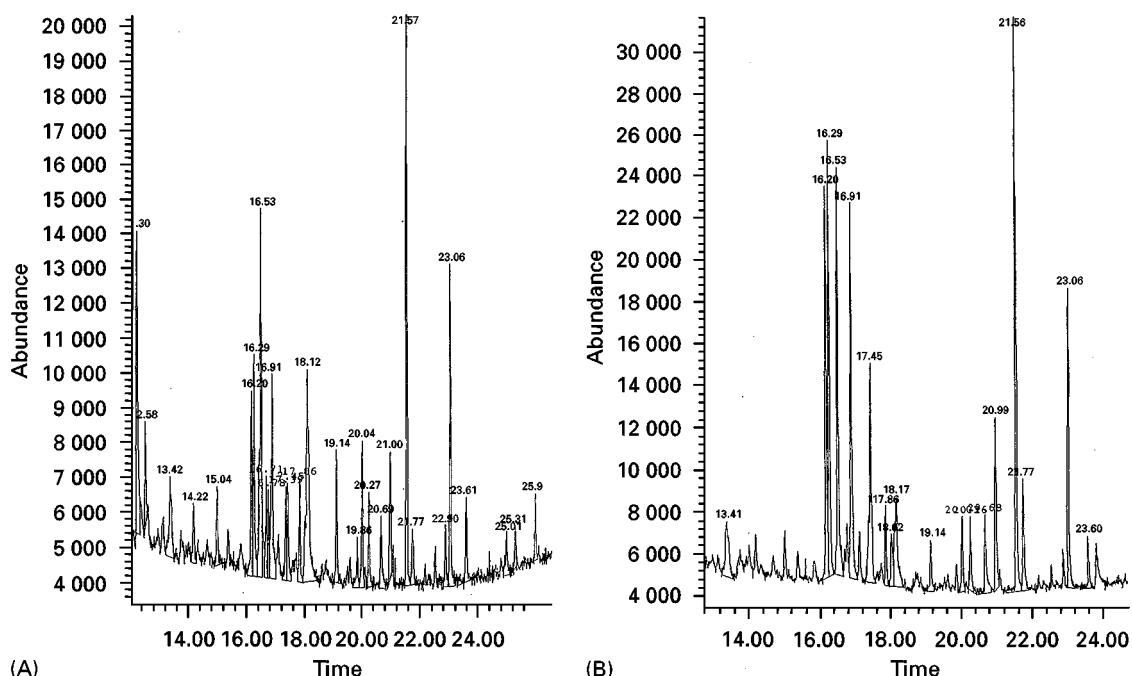

Figure 2 Chromatograms of samples removed from two works by William Blake: (A) white priming sample from *Spiritual Form of Nelson Guiding Leviathan* (1805–9); (B) green paint sample from *Body of Christ Borne to the Tomb* (1799–1800).

in an attempt to protect them from weathering and contamination and, though not classed as media themselves, their characterization may provide important evidence when determining the reasons for the ageing/degradation of works of art.

Varnish samples are commonly saponified prior to methylation, then the components separated on a capillary column with a linear temperature programme. Using mass spectrometry as a detection technique, two major peak groups can be seen, corresponding to the diterpenoid and triterpenoid components.

Waxes are stable materials comprising hydrocarbons and esters and, because of the virtual absence of polar groups, they can be analysed directly by high temperature capillary GC without the need for derivatization.

Reversed-phase High Performance Liquid Chromatography

The speed and sensitivity of reversed-phase high performance liquid chromatography (RP-HPLC) has led to significant developments in the analysis of proteins: RP-HPLC is now one of the most widely used techniques for the analysis of amino acids, since pre-column derivatization is possible with a selection of derivatizing agents and a variety of detection techniques can be employed. RP-HPLC lends itself well to conservation science, being particularly suitable for the analysis of the extremely small samples removed from works of art.

Phenylthiocarbamyl derivatives of amino acids in the hydrolysate of proteinaceous media samples have been separated on a C_{18} column using a ternary solvent system as the mobile phase (water–acetonitrile–acetate buffer).

Following hydrolysis of proteinaceous material removed from a series of Italian 15th-century painted panels, Halpine used phenyl isothiocyanate (PITC) for the derivatization of the amino acids, which were then separated on a C_{18} column using a binary solvent system of acetonitrile and acetate buffer (Table 2). The addition of nor-leucine as an internal standard facilitated the quantification of the amino acid components in the proteins, which in turn resulted in the characterization of a number of animal glue and egg/glue media. However, PITC-amino acid derivatives degrade in solution, so must be stored at low temperature prior to analysis.

PITC derivatives have also been analysed by RP HPLC when attempting to identify media samples which had been removed from a variety of French and Italian stone and wooden sculptures, frescoes and statues. Proteinaceous material was extracted from the matrices with sodium hydroxide and the subsequent analysis indicated the presence of gelatine and egg proteins.

9-Fluorenylmethyl chloroformate (FMOC) is a useful derivatizing agent for amino acids since it favours mild, aqueous conditions, reacts with both primary and secondary amino acids and is stable at room

Table 2 Percentage amino acid composition

Amino acid	Percentage amino acid composition							
	Control samples				Samples from panels

temperature for up to 2 weeks. The FMOc moiety is both highly fluorescent and a good UV chromophore, so absorption and emission detection techniques can be used. Detection methods are an important concern in conservation science in view of the very small samples available – FMOc is particularly useful since fluorescence is usually far more sensitive than UV absorption. Standard proteinaceous media and museum sample hydrolysates have been characterized as FMOc derivatives.

Other Chromatographic Techniques

Ion Exchange Chromatography

Ion exchange chromatography was first used for the analysis of samples from works of art in 1969 when the successful analysis of antique and modern art specimens was reported. The eluted amino acids were detected by optical density with ninhydrin, then the percentage amino acid composition was calculated for each sample. Samples of gelatine, casein, glair, tempera and even animal horn were characterized using this method.

The use of ion exchange chromatography in this particular area is problematic: the method of sample preparation is both lengthy and complex, pH gradients are difficult to control precisely and the required

sample size of paint is relatively large when put into the context of a specimen to be removed from a valuable work of art. Furthermore, museums and galleries are notoriously short of both money and space, thus specific single-purpose equipment is deemed unaffordable by many institutions.

Thin-layer Chromatography

TLC has been used on many occasions, particularly in the analysis of natural gum media – it is often used in conjunction with GC for such analyses but can provide useful information when used alone.

TLC has been used to characterize gum media taken from a 16th-century manuscript: hydrolysed gum samples were separated on silica plates, facilitating the subsequent identification of gum arabic.

Samples of binding media from paint layers were removed from three ancient Egyptian epitaphal stelae on wooden supports, then TLC was used to investigate the nature of the media, revealing the presence of gum tragacanth.

Pyrolysis–Gas Chromatography

Pyrolysis–gas chromatography (Py-GC) has been employed in the analysis of natural gum media from works of art. The distinctive pyrograms obtained for a series of standard gum samples enabled their identification and it was discovered that by pyrolysing the

complex gum-pigment mixed samples at 400°C, differences in peak patterns between standard samples and mixed samples were minimized. Sample identification is aided by the use of computational methods of pattern recognition.

Conclusions

When preparing to analyse a sample removed from a work of art, conservation scientists must select a technique which gives the maximum amount of information for the minimum amount of sample and sample preparation: it appears that RP-HPLC using FMOc as the amino acid derivatizing agent is the optimum analytical technique for the characterization of proteinaceous binding media, whilst GC is routinely used for oil-based media.

At present, GC analysis of silylated sugar residues is arguably the best method for the identification of natural gum media, and the use of mass spectrometry as the detection technique offers superior sensitivity and flexibility for these complex samples. However, this seems to be the least investigated area of analysis and significant developments in methodology which will further improve the sensitivity of the technique can be anticipated: this is of particular importance in the analysis of gum media since samples invariably contain no more than 10% binding medium, resulting in minute amounts of actual analyte in the samples. It is possible that microbore HPLC techniques may find a use in conservation science, since they are obviously suited to the minuscule samples routinely provided for analysis.

Simple qualitative techniques such as TLC may be sufficient to indicate the basic media type used in works of art, but as more and more works require some form of conservation or restoration treatment it is becoming increasingly important that the conservator has as much information as possible relating to the nature of the materials used in the work, in order to avoid damaging irreplaceable objects of artistic importance.

Chromatographic techniques provide reliable and accurate methods of analysis, suitable for use with the microscopic samples typically seen in this field of work. Further work should lead to simplification of methods of sample preparation – any improvements which mean that the size of samples required for analysis is reduced and that analyte losses are minimized would be welcomed by the conservation community.

ATMOSPHERIC ANALYSIS: GAS CHROMATOGRAPHY

A. C. Lewis, University of Leeds, Leeds, UK

Copyright © 2000 Academic Press

Introduction

The determination of both naturally produced and anthropogenic organic species in the atmosphere is a key area in atmospheric chemistry research. Nearest to the earth's surface, within the boundary layer of the troposphere, the determination of hydrocarbon species is important because of their ability to react rapidly with NO_x in the presence of sunlight to form photochemical smog. At the other extreme of the atmosphere in the stratosphere, remote measurements of very long-lived halogenated species are required because of their critical impact on ozone destruction. Species such as methane, present throughout the atmosphere, have importance as greenhouse gases and influence global climate and temperature change.

The wide range of both short- and long-lived species that are of interest in atmospheric science coupled to extremely low concentrations and a requirement often for *in situ* automated analysis has led to the development of many novel chromatographic techniques and methodologies. While some atmospheric species such as organic acids, peroxides and aldehydes have been determined using high performance liquid chromatography, the majority of species are analysed using capillary gas chromatography. The range of compounds that are of interest has resulted in almost every kind of detector finding a role within atmospheric analysis.

This article only deals with the analysis of species found in the gas phase, although many species present in the atmosphere are bound to particles or are in aerosol form. A vast number of methodologies for analysis of these species exist, although in common with gas phase species, gas chromatography plays a vital role in their analysis.

The range of techniques that are in use is so broad that a complete review of analytical methods is impractical. Many individual methods, however, have common components or key procedural steps and these will be discussed. A general outline of a typical atmospheric determination can be broken down into the following steps: sample acquisition, preparation, separation and detection. The first two stages, acquisition and preparation, often prove to be the most

challenging. A number of chromatograms obtained from atmospheric analysis are also presented in Figures 1–4. Figures 1 and 2 were obtained from an urban environment and Figures 3 and 4 came from a single field campaign held on the west coast of Ireland to study clean marine air.

Sample Acquisition

The initial step of sample acquisition is a far from trivial task in atmospheric measurements, and segregates a major grouping of techniques into either *in situ* or post-acquisition analysis. The ability to store an atmospheric sample is critical to the decision on whether analysis may be performed back in the laboratory or on-site immediately following acquisition. Stable species such as methane, carbon monoxide and chlorinated fluorocarbons may be stored successfully in sample vessels for many weeks without affecting sample integrity, and widespread measurements of these species have therefore been performed. Atmospheric degradation products, such as peroxyacetyl nitrate (PAN , $\text{CH}_3\text{C}(\text{O})_2\text{ONO}_2$), are so unstable, however, that analysis must be performed immediately. For many other important reactive species such as alkenes, monoterpenes and dimethyl sulphide, the storage of samples has been shown to lead to a degree of analyte losses due to reaction with co-sampled pollutants such as ozone and oxides of nitrogen. To overcome these problems of reaction during storage, many forms of scrubber (e.g. potassium iodide and glycerol to remove ozone) have been tested to remove such species without affecting sample integrity.

Much atmospheric sampling is performed using canister methods, filled either by vacuum release or by pumping sample into the canister using stainless steel or Teflon diaphragm pumps. For any sample to be stored successfully there must be minimal interaction with the canister walls and coating methods such as electropolishing, silica or Teflon coating are currently in use. The preparation and cleaning of canisters require careful attention and high vacuums are often applied together with elevated temperatures for periods of hours or even days. A similar method to canister samples is the use of collapsible Teflon or Tedlar sample bags. These bags may be filled by pump and returned to a laboratory for analysis using very similar procedures to those used with canister

Figure 1 Low molecular weight hydrocarbons including methane determined using an online activated charcoal adsorbent trap in a programmed temperature vaporization injector. samples. While generally of lower unit cost, the bag method often produces a greater degree of sample artefact and analyte losses.

Some low volatility species are less suitable for sampling using canister methods because of the increased possibility of analyte condensation on to the walls of the container. For this reason a second method of sample acquisition is widely used based on use of a solid-phase adsorbent as an analyte trap. The adsorbent used in the trap may be chosen to introduce an element of selectivity to the trapping mechanism, although in practice a trap-all approach is commonly used. Adsorbent traps allow for instrument automation that is not always possible with canister methods and such traps now form the basis of many national monitoring programmes in the urban environment, as well as automated instruments for research in very clean air.

A huge range of adsorbents is currently available from high surface area ($>1000 \text{ m}^2 \text{ g}^{-1}$) carbon-based materials with strong retention characteristics to lower surface area ($<50 \text{ m}^2 \text{ g}^{-1}$) polymers such as Tenax TA. While being relatively low cost compared to sample canisters, care is often required in the cleaning and preparation of sample tubes. Samples may be introduced to the adsorbent tubes either dynamically over short periods of time (typically minutes) or via diffusional sampling over longer periods (typically several days). Carbon-based adsorbents are suitable for a wide range of species ranging from volatile hydrocarbons and CFCs to organic nitrates. Polymeric materials are used mainly for the concentration of low volatility species such as aromatics and monoterpenes in air, although compounds as large as two and three ring polycyclic aromatics may also be successfully trapped and desorbed from the gas phase.

Sulfur species trapping is often performed via chemisorption on to gold wool traps that provide a stable matrix for the sample to be stored for reasonable periods of time.

The complete retention of all target analytes on the adsorbent bed must be carefully evaluated and calculation of retention volume (often referred to as breakthrough volume) is essential. For sampling very volatile species (for example ethane or ethene) the retention volume for an adsorbent system is often the critical factor in determining system sensitivity. Trapping at sub-ambient temperatures is commonly employed to increase the maximum sample volume, often using liquid nitrogen or carbon dioxide. For operation of any instrument in a field location, the supply of these coolants may be a problem and modern instruments often now employ Peltier coolers.

Sample Preparation and Injection

Removal of Water

The inevitable presence of water in atmospheric samples and its removal prior to sample analysis is a complex area. In certain circumstances its presence may be both beneficial, e.g. with canister samples where it occupies the active sites on the canister walls, or detrimental, e.g. where it affects analysis in some way. Alumina porous layer open tubular (PLOT) columns are particularly affected by moisture in the sample, and large changes in stationary phase affinity occur when water is introduced. Detectors such as mass spectrometers are also extremely sensitive to water introduced with the sample and high background noise may result. Even the flame

ionization detector can be affected by injection of water, and the flame may be extinguished when water elutes from the column.

Many forms of selective water removal exist, the simplest of which is the use of condensation traps or stripping coils. Losses of low boiling molecular species are insignificant although condensation of higher boiling organic material may arise at low condensa-

tion temperatures. Inorganic adsorbents are also commonly used, notably potassium carbonate and magnesium perchlorate. Adsorbents such as these, however, have limited capacity and often require frequent regeneration or replacement. A combination of initial condensation and second stage adsorbent scrubber often provides sufficient capacity to dry a sample stream of air for many hours or days. Con-

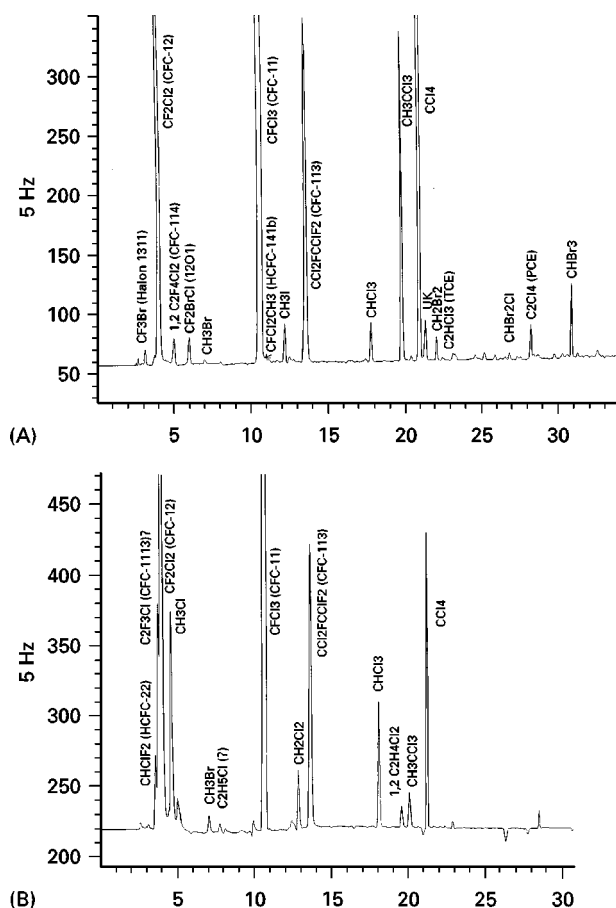

Figure 3 CFCs and halon species in clean marine air determined using an online Carbosieve micro adsorbent trap and direct injection to capillary GC. Detection by dual ECD/oxygen-doped ECD. tinuous drying may be achieved using permeation membranes such as Nafion. These forms of driers operate by means of a concentration gradient across a membrane that is permeable only to highly polar material such as water. A counter-current of dry gas is passed around the outside of the membrane as a sheath gas and carries moisture away to waste. However, this type of drier is unsuitable for samples where the quantitation of polar materials is required.

Direct loop injection High concentration atmospheric species require the least amount of sample preparation, often only the removal of excess water from the sample. Methane, carbon monoxide and N_2O analyses are performed simply by filling a known volume injection loop, followed by direct injection into the analytical column. Backflushing is

often then performed to remove the remaining components from the analytical column. A further example of direct loop injection is in the analysis of PAN where, due to thermal decomposition of the sample, analysis must be performed *in situ*. It is performed using direct loop injection to a cooled isothermal pre-column followed by a short analytical capillary column coupled to an electron capture detector. An ancillary measurement of carbon tetrachloride is often gained from using this approach.

Sample concentration methods Whether an atmospheric sample is collected using adsorbent or canister techniques, several stages of sample preparation are required prior to injection into the analytical column. The sheer size of sample – often many litres – precludes any form of direct injection except in the case of the high concentration species described earlier, making sample concentration a vital step prior to injection.

Canister samples require complete concentration prior to introduction to the capillary column.

Analytes are removed from the canister via either internal canister pressure (for pumped-in samples) or vacuum pump (for atmospheric pressure samples) over a cryogenic trap. Liquid nitrogen is most commonly used but liquid argon has been used to reduce the amount of oxygen retained in the focusing stage. The concentration zone may consist of a packed tube containing either an absorbent such as Tenax TA or glass beads or it may simply be empty stainless steel tubing. Since the concentration stage is at such low temperatures, the majority of water vapour in the sample must be removed prior to focusing in order to stop blockage of lines with ice. Once a sufficient volume has been collected on the focusing trap, the trap is generally flash heated either electrically or by using hot water. This results in a very sharp band of compounds being introduced to the head of the analytical column.

With adsorbent tube analysis the collected analytes are generally thermally desorbed either directly on to the analytical column (in the case of programmed temperature vaporization injection), or on to a focusing cold trap. The desorption temperature is generally defined by the maximum temperature that the adsorbing material can support. For polymeric adsorbents this may be relatively low ($<250^{\circ}\text{C}$) while carbon-based materials may support desorption at temperatures of 500°C or higher.

If a programmed temperature vaporization (PTV) injector is used, the desorption may be sufficiently rapid ($>15^{\circ}\text{C s}^{-1}$) so that initial column focusing is sufficient to obtain well-resolved peaks. If the desorption from an adsorbent tube is relatively slow then a focusing step is used, with a similar concentration mechanism to that used with canister samples. Once again, water must be removed from the sample since it may affect the column or the detection system.

While the majority of species are thermally desorbed from the trap to the analytical column, a few types of compounds require solvent extraction prior to syringe injection. Organic nitrates fall into this class along with higher molecular weight polycyclic aromatic compounds that may suffer from incomplete or slow thermal release.

Separation of Atmospheric Samples

While a number of specific applications utilize packed columns (notably in the analysis of methane, CO and N_2O), current methods for the separation of atmospheric components are performed almost exclusively using capillary column gas chromatography.

The few applications remaining where packed columns are in use, generally employ molecular sieve packings for the separation of permanent gas species.

With the introduction of Al_2O_3 PLOT columns, fast high resolution analysis of even the highest volatility species has been made possible and many applications that previously used packed column GC are now being performed using capillary columns.

Where only one species is to be determined simple isothermal separations may be used, often in conjunction with a column backflush step. The analysis of PAN is an example of this where a short backflushing pre-column is used prior to a 10 m analytical column. A simple two-dimensional separation has also been proposed for PAN using heart-cutting.

The wide magnitude of analyte volatilities encountered imposes limits on the range of species that can be successfully separated on a given column. PLOT columns are used widely for the analysis of $\text{C}_1\text{--C}_7$ hydrocarbons and some high volatility halogenated compounds. The retention characteristics of this type of column are not favourable for the analysis of oxygenated compounds, and water often plays a significant role in degrading the quality of any PLOT column separation. Very strong retention of higher boiling species leads to extensive peak broadening coupled with lengthy analysis times.

Analysis of higher molecular weight species, including volatile organic compounds (VOCs), CFCs and hydrogen-containing chlorofluorocarbon replacements (hCFCs), aromatic and monoterpene compounds, has commonly been performed with nonpolar (methylpolysiloxane) or slightly polar (5% phenyl methylpolysiloxane) 1–5 μm -thick film capillary columns, 0.32 mm i.d. by 50 m long. Wide bore, 0.53 mm i.d. columns are often used where desorption is direct from a preconcentration trap to the analytical column. For the analysis of complex hCFC mixtures in the atmosphere, columns as long as 100 m have been reported.

To improve retention of volatile VOCs on thick film siloxane columns, without use of sub-ambient cooling, operation with columns containing films up to 15 μm thick have been reported. Band broadening effects through stationary phase diffusion become significant with films of this thickness and this approach has not been widely adopted. The highest molecular weight gas phase species such as naphthalene, fluorene and anthracene may be separated efficiently only on thinner film non-polar columns with film thicknesses of typically 0.25–0.5 μm .

Organic nitrate species in the atmosphere may also be determined using capillary GC with either charcoal adsorbent traps, extracted with aromatic organic solvent or via direct cryofocusing from a canister sample. Lengthy analysis times can result due to the necessity of using combinations of columns to achieve full separation of target analytes although commonly

moderate polarity 50% phenyl/50% methyl polysiloxane columns are used.

Detection Systems

Even the highest resolution capillary columns often have insufficient peak capacity to resolve all components in a typical atmospheric sample. Since selectivity in trapping is not always possible, selectivity in detection is a useful tool in the simplification of atmospheric analysis.

The flame ionization detector (FID) is by far the most commonly used detector in atmospheric analysis by GC since it offers high sensitivity, extremely wide linearity and good reliability. Using well-cleaned fuel gases coupled to low noise electrometer circuitry it is possible to determine amounts down to 1 pg s^{-1} . With a typical sample volume of 1 L, detection limits for individual species may be in the low parts per trillion range (10^{-12}). Calibration can be performed with relative ease but the complexity of samples can make peak identification difficult. Methods for alkene/aromatic analysis utilizing selective response from the photoionization detector (PID) have been proposed although they are not in widespread use.

Mass spectrometry offers obvious solutions to problems of compound identification but the operation of currently available bench-top MS in full scan mode often has insufficient sensitivity for trace level measurements. Spectral information obtained from GC/MS of atmospheric hydrocarbons often leads to highly similar fragmentation patterns and assists little in the identification of isomeric species. Similarly, identification of monoterpene species can only be confirmed through a combination of both spectral information and retention time data.

While MS of hydrocarbon species in clean air is often unsuccessful when operating in full scan mode there is sufficient sensitivity and resolution to allow for detection of long-lived CFC species. Long-term monitoring of these species has been performed by GC-ion trap detection in the worldwide MS-GAGE (global atmospheric gases experiment) network. In single ion mode, femtogram sensitivities can be achieved and this approach has been used for field monitoring of naturally produced trace level iodo- and bromo- compounds.

More commonly used for CFC measurements in the atmosphere is the electron-capture detector (ECD) that offers high sensitivity to certain species plus high selectivity over hydrocarbon compounds. GC-ECD measurements require careful calibration due to the great variation in response to halogenated species, although their high stability allows gas standards to

be used over many years. Some halogen-containing species of interest (e.g. CH_3Cl , CHF_2Cl , CH_2Cl_2) have a relatively poor ECD response and the use of the oxygen-doped ECD to enhance their response has been successful and is demonstrated in Figure 3. The determination of some nitrogen-containing species is also performed using ECD, notably in the areas of organic nitrate analysis and the determination of PAN. Organic nitrate analysis using ECD is often complicated by the co-elution of halogenated compounds, so often a nitrogen-specific detector such as the chemiluminescence detector is used in parallel.

Detection of CO is generally performed using the reduction gas detector (RGD) where hot HgO reduction with one CO molecule releases one Hg molecule from a catalytic bed. The Hg molecule released is then detected by UV absorption.

The analysis of sulfur compounds in the atmosphere, in particular dimethyl sulfide (DMS), has often been performed using a combination of GC with sulfur selective detection to overcome problems of insufficient chromatographic resolution. Flame photometric detection (FPD) has been used extensively in the past although signal quenching by co-eluting hydrocarbons results in drastically reduced sensitivity. The *Hall* detector or electrolytic conductivity detector (ELCD) has also been used for atmospheric determinations although it requires regular maintenance making it unattractive for an automated instrument. Emerging methods are now taking advantage of significant advances in bench-top atomic emission detectors (AED). The multielemental nature of the AED offers significant advantages in atmospheric measurements both in terms of sensitivity (sulfur $- 2 \text{ pg s}^{-1}$), and where concurrent emission line measurements for carbon and hydrogen may provide information on empirical formulae of unknown species. The sulfur chemiluminescence detector, which is a more recent technique that offers extremely high sensitivity and selectivity, may yet find an important role in atmospheric sulfur analysis.

The analysis of oxygenated species in the atmosphere is one of the least studied areas using gas chromatography. It is an area of fundamental significance where species may be present in the atmosphere as direct emissions or as degradation products of olefins. While most aldehydes and ketones may be successfully separated using GC, sample preparation and analyte detection are the key problem areas. Sample preparation is an area where new adsorbents may provide selective concentration of polar species simplifying the chromatogram produced. Detection of oxygenates is a further difficulty due to their often very low response in both ECD and FID. Use of elemental specific detection such as AED offers

some potential in atmospheric oxygenate analysis although AED sensitivity for oxygen is only around 100 pg s^{-1} . Detectors such as the helium ionization detector (HID), which produce a nonselective high sensitivity response to these types of compounds, may in future allow on-line measurements of oxygenates with GC, assuming sufficient chromatographic resolution or trapping selectivity can be obtained.

Future Work

Gas chromatography has an important role to play in monitoring mankind's emissions into the atmosphere and exploring the natural balance of biogenically released materials. New developments in injection technology and adsorbent materials will allow a greater number of species to be determined automatically in field locations. Development in column technology to reduce the effect of moisture on chromatographic separation and broaden the range of volatilities that may be separated on a given column will also bring significant benefits. Improvements in detector sensitivities and reliability (notably bench-top MS) will determine which of the many available detectors become standard in the next generation of atmospheric instruments.

BACTERIOPHAGES: SEPARATION OF

P. Serwer, The University of Texas Health Science Center, San Antonio, TX, USA

Introduction

Bacteriophages are viruses that infect bacteria. Historically, interest in bacteriophages was first

generated by the possibility of using bacteriophages as biological antibiotics. This interest is periodically revived when difficulties are encountered with the use of chemical antibiotics. Interest in bacteriophages was also generated by both the short life cycle and the simple (short) genome of bacteriophages. These characteristics were useful in developing the science of molecular genetics. Bacteriophages were a favourite

for asking questions about transfer of biological information via DNA replication, transcription (copying of RNA from DNA) and translation (using the information in RNA to assemble proteins). Today, bacteriophages are used to carry small pieces of the DNA of higher organisms. The purpose is to determine the nucleotide sequence of the pieces and, ultimately, the nucleotide sequence of the whole genome of higher organisms. Basic science uses bacteriophages as models for understanding how separate molecules assemble to form a complex structure. The questions asked in these studies are fundamental: How do biological motors work? How is specificity maintained in intermolecular binding? How is accuracy assured during assembly? To what extent is biological form determined by either pathway of assembly or energetics of the final structure? Are errors corrected during assembly of biological macromolecules? Are separate biochemical processes integrated in the context of the interior of a cell? Pursuit of the answers to all these questions requires purification of bacteriophage particles.

Purification of both bacteriophages and bacteriophage-like particles is also needed for other types of study. Bacteriophage-like particles are present in both lakes and oceans. Some are true bacteriophages. Others are viruses that infect algae, rather than bacteria. Environmental biologists detect and sometimes purify these particles without knowing what they are. Purification helps establish what they are, both biologically and chemically. Finally, bacteriophages are model viruses. Study of the evolution of bacteriophages helps in the understanding of the evolution of other viruses, including pathogenic viruses. A major advantage of studying bacteriophages is their comparatively short life cycle. For example, bacteriophage T7 has a 13 min life cycle at 37°C and a 25 min life cycle at 30°C. The host cell is *Escherichia coli*. Most other bacteriophages that infect *E. coli* have life cycles less than 60 min at 37°C. Thus, studies of evolution are achieved more quickly than they are with any other organism. Also, the short life cycle of bacteriophages reduces the time needed to grow them.

Growth of Bacteriophages

Bacteriophages are grown in either gelled or liquid solutions of nutrients. Gels are made of the polysaccharide, agar. Gel-embedded infected cells are used to count viable bacteriophage particles. The procedure is to embed bacteriophages in the gel, together with host cells. The number of host cells is much greater than the number of bacteriophages. This gelled mixture is incubated to replicate the cells and infect them. A bacteriophage particle infects a growing host cell

while in the gel. The cell bursts at the end of the infection. Light-scattering (turbidity) decreases when the infected cell bursts. All progeny of a single bacteriophage particle remain in a restricted region of the gel. This region is comparatively clear (nonturbid). The clear region is called a plaque. A viable bacteriophage particle is assayed by the formation of a single plaque on a glass or plastic Petri dish or plate which holds the gel with plaques. Plaques are counted after incubating viable bacteriophage particles with host cells. The number of viable bacteriophage particles per plate is small enough (usually 100–2000) so that overlapping plaques do not cause difficulty in counting. The number of plaques is multiplied by a dilution factor, if the bacteriophage particles had been diluted before assay. Bacteriophage plaques are illustrated in Figure 1.

Incubation of a host–bacteriophage mixture in a gel can also be used to prepare large numbers of bacteriophage particles before purification. The bacteriophages produced are sometimes called a plate stock. Preparing of bacteriophage particles via large volume (> 100 mL) plate stocks is not efficient (in time and cost), in comparison to preparing bacteriophage particles via infection in liquid culture. However, some bacteriophages which do not grow well in liquid cultures grow comparatively well when prepared as a plate stock. Thus, plate stocks are sometimes used for the growth of bacteriophage particles before purification. To remove bacteriophage particles from the gel of a plate stock the gel is minced

Figure 1 Plaques of bacteriophage T7. A Petri plate is filled with a 1% agar gel in an enriched growth medium. Subsequently, 0.7% molten agar in the same enriched medium is mixed with both host bacteria and bacteriophage particles. This mixture is spread on the 1.0% gel. The plate is incubated at 37°C. A plaque forms at the position of a single bacteriophage particle.

with either a glass rod or a spatula and the minced gel is incubated with buffer. The bacteriophage particles diffuse out of the gel, into the buffer during this process. Centrifugal pelleting is then used to remove the pieces of gel, together with pieces of the host bacterium. Some bacteriophages are pelleted with the gel. Thus, the pelleted pieces of gel are resuspended in buffer and then pelleted a second time. This process is called washing. Washing is typically performed two or three times. The supernatant solutions are pooled to produce a clarified plate stock.

Details of plate stock preparation vary slightly among the various bacteriophages. A bacteriophage best prepared by plate stock is bacteriophage G. Bacteriophage G is the largest bacteriophage (known to the author) that can be grown in culture. Bacteriophage G has a double-stranded DNA genome 670 kilobase pairs long. Bacteriophage G can be grown in liquid cultures, but results are erratic and greater success has been achieved with plate stocks. Typically, plate stocks of bacteriophage G are clarified by centrifugation at 5000 rpm in a 250 mL bottle (or the equivalent; centrifugal force at the bottom of the bottle is 3800 g). This speed is doubled (centrifugal force is quadrupled) in the case of smaller bacteriophages that don't sediment as quickly as bacteriophage G. Pelleting the bacteriophage particles (or aggregates of them) works against the objective of clarifying a plate stock.

Maintaining the stability of the bacteriophage particles is an objective at all stages of purification. Known bacteriophages are stabilized by the presence of divalent cations. Magnesium is usually used. Thus, magnesium should be present in the buffer. The presence of $0.001 \text{ mol L}^{-1} \text{ MgCl}_2$ is usually sufficient for stability. Some salt (usually NaCl) should also be present. Some bacteriophages increasingly adsorb to fragments of host cell, as the salt concentration is lowered. Thus, salt concentrations are sometimes raised from the typical 0.1 mol L^{-1} to 0.5 mol L^{-1} or more. Adsorption to host cell debris can either inactivate a bacteriophage particle or cause it to pellet with the fragments of gel.

Storage

Plate stocks are also sometimes preferred when a new bacteriophage is isolated. The new bacteriophage might have been isolated from the wild. It might also have been produced by genetic modification of a previously isolated bacteriophage. A plate stock made with a single plate is a rapid and simple way of preserving this new strain. Preservation is completed by freezing a clarified plate stock. Freezing (typically at -70°C) is used to prevent inactivation during storage for periods of years to decades. A cryoprotectant

is added before freezing. Glycerol (10%) can be used as a cryoprotectant. Alternatively, a high molecular weight cryoprotectant can be used. A high molecular weight cryoprotectant sometimes used is 10% dextran, average molecular weight = 10 000. High molecular weight cryoprotectants are less likely to enter a bacteriophage particle. Therefore, high molecular weight cryoprotectants are less likely to cause bacteriophage particles to burst from osmotic shock during thawing. Osmotic shock during thawing occurs because freezing causes nonuniformity in the concentration of cryoprotectant. If the bacteriophage particle is in a region of comparatively low cryoprotectant concentration, an outward osmotic pressure gradient will develop. This is a demonstrated cause of inactivation of bacteriophage T4 by freeze-thawing.

Growth in Liquid Culture

A bacteriophage is usually grown in liquid culture, when the purpose is either chemical or physical characterization of either the bacteriophage or its nucleic acid. In this case, amounts in the 1–50 mg range may be needed. Either simple, well-defined media or enriched media are used. A simple, well-defined medium might have glucose as the primary (sometimes only) source of both carbon and energy. The medium is typically buffered with phosphate. The medium is supplemented with ammonium chloride to provide nitrogen for proteins. Other salts are also added. Both magnesium sulfate and calcium chloride are added after sterilization by autoclaving. Apparently, some requirements, such as iron, are present in sufficient quantity as contaminants. Alternatively, an enriched, but less well-defined, medium can be used. The major components of an enriched medium are often both tryptone and an extract of yeast cells.

Some bacteriophages are more easily (and more inexpensively) grown in minimal medium. This is true for some lytic double-stranded DNA bacteriophages, for example. A lytic bacteriophage always produces progeny when it infects a cell. The counterpart of a lytic bacteriophage is a lysogenic bacteriophage. A lysogenic bacteriophage may or may not produce progeny. The lysogenic bacteriophage genome both remains in and replicates with the host, if progeny are not produced. This state is called lysogeny. Lysogeny can simplify growth of some bacteriophages, as described below. Growth of a lytic bacteriophage, but not a lysogenic bacteriophage, encounters the following problem: cells are infected at a low ratio of bacteriophage particles to host cells, typically 0.01–0.1. Multiple cycles of infection occur. Therefore, the concentration of cells during the final (and most critical) cycle of infection is hard to control. Overgrowth of

cells can result in a suboptimal yield, because of inadequate aeration. Undergrowth of cells can result in suboptimal yield, because of the low concentration of cells. The more rapidly cells grow, the more difficult controlling their concentration during the last cycle is. Cells grow more slowly in minimal medium (typical doubling time = 1.5–2.0 h for *E. coli* at 30°C) than they do in enriched medium (typical doubling time = 30–40 min for *E. coli* at 30°C). Thus, the infection is more easily controlled in minimal medium. None the less, other factors are also involved. Some experimentation with growth medium is required to optimize conditions of growth, when these conditions have not been previously optimized.

Growing lysogenic bacteriophages is usually easier than growing lytic bacteriophages. Lysogenic bacteriophages can be made to leave a state of lysogeny and enter a lytic cycle. Some mutants will do this when the temperature is raised. Thus, growth of lysogenic bacteriophages (bacteriophages λ and P22, for example) can be simplified. Host cells in a state of lysogeny are grown to an optimal concentration. The temperature is raised to induce the lytic cycle. The temperature is then lowered to an optimal temperature for growth. This process is useful for producing bacteriophage particles in large amount. It is also useful for producing other components of bacteriophage-infected cells. For example, some components of bacteriophage-infected cells retain their metabolic activity when infected cells burst (lyse is a frequently used synonym for burst). These activities include packaging of double-stranded DNA in bacteriophage capsids. Thus, a fragment of foreign DNA can be cloned by, first, incorporating the fragment in a bacteriophage genome, and, then, packaging the DNA *in vitro* by incubating the DNA in an extract of lysed, infected cells. Extracts of lysed, bacteriophage-infected cells can sometimes be used for incorporating the foreign DNA, as well as packaging it. An extract can be made by use of a lytic bacteriophage, as well as a lysogenic bacteriophage. The process is, however, less time- and resource-consuming with a lysogenic bacteriophage.

Equipment for Large-Scale Growth of Bacteriophages in Liquid Culture

Small scale (1–1000 mL) liquid cultures are grown in typical laboratory glassware. A flask is sometimes used, with aeration by shaking. Alternatively, a bottle is used with aeration via a bubbler and forced air. The latter alternative is simpler, less expensive and less space-consuming. A reliable shaker is needed in the former case; a source of forced air is needed in the latter. A reliable and reliably clean source of forced

air is an aerator designed for use with tropical fish. The use of forced air is scalable to at least a 15 L culture. Shaking is scalable to roughly a 1 L culture.

The control of temperature can be achieved via several routes. A temperature-regulated fermentor with forced air can be used. The cost and inconvenience can, however, be dramatically lowered by using a bottle in a temperature-controlled water bath. Even a bottle in a temperature-controlled, water-filled sink can be used. In the latter two cases, a bottle with sterile medium and bubblers is aerated via forced air.

First Stage of Purification

The targeted degree of purification varies with the intent of the investigator. The minimal purification is removing large fragments of the host cell. Pelleting in a centrifuge is used. This stabilizes the bacteriophages by preventing adsorption of the bacteriophages to fragments of host cell membrane. Pelleting is typically done immediately after lysis for small (< 1 L) cultures. Pelleting is sometimes delayed until after precipitation of bacteriophage particles for large cultures. The precipitation is performed by both raising the salt concentration (typically to 0.5 mol L⁻¹) and adding a high molecular weight polyethylene glycol. Details vary among the different bacteriophages. The precipitation concentrates bacteriophage particles for subsequent steps in purification. Alternatively, bacteriophage particles can be concentrated by pelleting, without precipitation. The newer centrifuges can pellet bacteriophages in increased volume and decreased time. Bacteriophages in eight 50 mL tubes can now be pelleted in 1–4 h. The time depends on how rapidly the bacteriophage particles sediment at any given speed of centrifugation.

Subsequent Stages of Purification

Concentration and partial purification of bacteriophage particles are achieved in the first stage of purification. The subsequent stages can, in theory, be essentially any procedure of purification used for other biological macromolecules. However, in practice, the simplest, highest yielding, highest volume procedure has been found to be centrifugation. Three types of centrifugation are used, sometimes in tandem. The details of procedure vary with both the properties of the bacteriophage and the purposes of the investigator.

Buoyant Density Centrifugation

Buoyancy is a familiar concept to anyone who has learned to swim. Buoyancy can be used to purify any

macroscopic object by placing the object in solution that continuously varies in density. Gravity will drive the particle to the region of the density gradient that has a density equal to the density of the particle (isodense region). This concept also works for bacteriophages. However, bacteriophages are small. They are so small that ultracentrifugation is needed to drive them to an isodense region (a process called buoyant density centrifugation). Thermally driven motion (diffusion) randomizes the position of the bacteriophage particles in the absence of centrifugation. Even if diffusion did not occur, the bacteriophage particles would take impractically long to find their isodense region, if centrifugal force were not applied. Buoyant density centrifugation is performed by mixing bacteriophage particles with a solute that will form a density gradient when centrifuged ('before' column of the first row of **Figure 2**; the sample is grey). The density gradient forms because the solute, like the bacteriophage particles, is driven in the direction of the centrifugal force. The motion caused by centrifugal force eventually achieves equilibrium with thermal motion. The result is a density gradient. The bacteriophage particles are driven to an isodense region of the gradient ('after' column of the first row of **Figure 2**; the sample is black). Comparatively small ions (or molecules), like caesium cations, form the

most linear density gradients. Caesium chloride is the most frequently used compound for fractionating bacteriophages by buoyant density centrifugation.

The word isodense means same density. But, what is the density of a bacteriophage particle? Can this density vary with position in a density gradient? This density not only can, but does, vary with position in a density gradient. The density varies because the anhydrous components of the bacteriophage are not the only components, from the perspective of buoyant density. The bacteriophage also contains both water- and density-forming solute. The concentration of water inside the bacteriophage is not necessarily the same as the concentration outside the bacteriophage. The bacteriophage nucleic acid sometimes binds a large amount of solute-free water, for example. But, this concentration does vary with the concentration of water outside of the bacteriophage. Analysis of this situation is beyond the scope of this article. This analysis is not critical for achieving practical results. However, it is critical for interpreting densities in terms of a particle's composition.

Many studied bacteriophages consist only of a protein capsid that contains a nucleic acid genome. The capsid has a density of roughly 1.3 g mL^{-1} when centrifuged to an isodense region in a caesium chloride density gradient. Double-stranded DNA has a density of roughly 1.7 g mL^{-1} . Both these densities vary slightly with detailed composition. Double-stranded DNA bacteriophages are, in general, roughly 50% DNA, 50% protein. The density of these bacteriophages is 1.5 g mL^{-1} . This density is halfway between the density of protein and the density of DNA. This relationship is, however, not an intrinsic feature of densities. Its source is roughly equal hydration of DNA and protein in caesium chloride density gradients. These two hydrations are usually not equal.

Buoyant density centrifugation has the following limitation. Low molecular weight contaminants (molecules of RNA, unassembled proteins) diffuse so rapidly that they contaminate the bacteriophages, even though their density is different. Thus, bacteriophage purification procedures often have one stage at which particles are fractionated by size.

Rate Zonal Centrifugation

Rate zonal centrifugation fractionates particles by both size and shape. The procedure is to layer a sample in a restricted zone on top of a pre-poured density gradient. The density gradient is then centrifuged. All particles migrate into the density gradient, because the density gradient has only densities much lower than the densities of the particles being centrifuged (illustrated in the second row of **Figure 2**). The

Figure 2 Purification of bacteriophage particles by ultracentrifugation. The three rows illustrate the three types of ultracentrifugation described in the text. The appearance of a centrifuge tube before centrifugation is shown in the column labelled before. The appearance of the same centrifuge tube after centrifugation is indicated in the column labelled after.

particles are fractionated primarily by size and shape. The larger a particle is, the more rapidly it sediments. The more spherically symmetrical a particle is, the more rapidly it sediments. Bacteriophages sediment much more rapidly than unassembled proteins and RNA. Thus, bacteriophages are separated from these particles by a single rate zonal centrifugation in a sucrose gradient. Some fragments of host cells co-sediment with bacteriophage particles. However, these fragments have a variable rate of sedimentation. The bacteriophage particles have a unique rate of sedimentation. Therefore, separation from most of these fragments occurs.

Rate zonal centrifugation has the following limitation. The sample occupies a small region of the centrifuge tube at the start of fractionation. Furthermore, the sample becomes less concentrated during fractionation. Thus, the amount of sample is more limited when compared to the amount fractionated by buoyant density centrifugation. During buoyant density centrifugation, the sample occupies the entire centrifuge tube at the start of fractionation. The sample becomes more concentrated during fractionation. Thus, rate zonal centrifugation is usually not the procedure of choice. However, some bacteriophages (including bacteriophage G) are not stable when centrifuged in caesium chloride density gradients. Rate zonal centrifugation is a reasonable alternative in this case. Unstable bacteriophages have been stabilized by including polyethylene glycol in the density gradient used for rate zonal centrifugation.

Combined Buoyant Density and Rate Zonal Centrifugation

Advantages of buoyant density centrifugation are combined with advantages of rate zonal centrifugation when the following hybrid procedure is used. A comparatively broad zone of sample is layered on a pre-formed caesium chloride density gradient (before column of the third row of Figure 2). The caesium chloride density gradient had been formed before centrifugation, by successfully layering 3–5 caesium chloride solutions. These solutions decrease in density, from bottom to top. The rapid diffusion of a caesium cations converts the discontinuous gradient (called a step gradient) into a more continuous gradient. The step gradient with layered sample is centrifuged until bacteriophage particles reach an isodense position in the gradient (after column of the third row of Figure 2). Thus, the advantages of buoyant density centrifugation are achieved: increase in the sample's concentration and fractionation by density. On the other hand, the advantage of rate zonal centrifugation is also achieved: separation of bacteriophage particles from rapidly diffusing components of the cell.

The advantages of a caesium chloride step gradients make them a method of choice for purifying many bacteriophages. A single centrifugation is sometimes sufficient to achieve the purity needed. Alternatively, a buoyant density centrifugation can be performed after centrifugation in a step gradient. Increase in concentration of the sample is achieved by combining bacteriophages from several step gradients in a single buoyant density gradient.

Nondenaturing Gel Electrophoresis

Bacteriophage particles can be fractionated by electrophoresis through gels. This procedure is called nondenaturing gel electrophoresis because the bacteriophage particles are intact (infective) during electrophoresis. In contrast, other procedures of electrophoresis are used to analyse the components of disassembled bacteriophage particles. The gels used for nondenaturing electrophoresis must have pore sizes large enough to admit bacteriophage particles (30–90 nm in radius). Polyacrylamide gels can be made dilute enough to achieve the needed pore sizes. However, these polyacrylamide gels are very weak and difficult to handle. Agarose gels achieve the needed pore sizes with gels that are easy to handle. Agarose has been the gel-forming compound most frequently used to fractionate bacteriophages (and other viruses) by nondenaturing gel electrophoresis.

Gel electrophoresis fractionates any spherical particle by two properties of the particle: the average electrical surface charge density (σ), and the radius. The value of σ is the sole determinant of the electrophoretic mobility (= velocity/electrical field) in the absence of the gel, within experimental accuracy. For example, a dimer of a bacteriophage capsid has an electrophoretic mobility indistinguishable from that of a capsid monomer, when the electrophoretic mobility is extrapolated to a gel concentration of zero. In theory, the value of σ will be the sole determinant of gel-free electrophoretic mobility, for all conditions likely to be encountered during the analysis of bacteriophage particles. Changing the value of the particle's radius will, however, change its electrophoretic mobility during electrophoresis through a gel. The larger the radius is, the more retarded the particle will be by the fibres that form the gel.

The fractionation by σ is independent of fractionations achieved by either buoyant density or rate zonal fractionation. Thus, nondenaturing gel electrophoresis can differentiate particles not differentiated by any procedure of centrifugation. The result has been the finding that at least one bacteriophage (T7) exists in more than one state. The different states appear to have evolved to improve the survivability of T7.

Figure 3 Nondenaturing gel electrophoresis. A horizontal gel with samples loaded is illustrated in the before panel. The same gel with stained, fractionated bacteriophages is shown in the after panel. The arrow indicates the direction of electrophoresis.

In practice, gel electrophoresis can be performed by the following procedure:

1. An agarose gel is cast in a horizontal orientation (before column in **Figure 3**). The gel has sample wells for placing the sample (indicated in **Figure 3**).
2. The gel is submerged beneath an electrophoresis buffer. The pH should be close to the pK_a of the buffer. The gel chosen should not adhere to the bacteriophage particles. Agarose can be purchased at several levels of purity. Several agarose derivatives and mixtures can be purchased. Some nonagarose polysaccharides can also be used for electrophoresis.
3. The sample is placed in a sample well. The sample contains an uncharged compound (glycerol, sucrose, a polyethylene glycol, for example), in order to prevent the sample from floating.
